Christiania and Bergen. The scenery of the Valdres and Leardal was unique in its way, and if, to some extent, it lacked the magnificent waterfalls that rendered the Romsdal so attractive, and which he endeavoured to illustrate on the occasion of his first lecture, he ventured to think the absence was compensated in the ever-varying and majestic character of the scenery at almost every point. At the present time all obstacles to comfortable travelling had been overcome; good conveyances can be hired, and excellent food and sleeping accommodation obtained, generally speaking, at a moderate cost.

"He intended on this occasion to treat his subject in a popular manner, and in order to make it as interesting as possible, proposed to give a representation of their actual tour, starting from Birmingham."

The lights having been turned down, a picture of the Grand Hotel, the headquarters of the Society, was projected on the screen (sixteen feet), powerful dissolving lanterns being used, and was immediately followed by a view of the interior of New-street Railway Station; this was a very difficult subject for the camera. The coupling of the engine to, and mimic departure of the train for Hull proved most realistic, and was awarded well-deserved applause. Representations of the train travelling at full speed, the arrival at Hull, and sailing of the Wilson Line steamship *Angelo* for Christiania followed, several amusing and interesting incidents on the voyage receiving due notice. Mr. Jacques spoke of the kindness of Captain Johnson, whose name was so well known by all Norwegian travellers.

After pointing out the proposed route on two well-defined maps, views of Christiansands were shown, also of the Christiania Fjords, a glimpse of which tourists generally miss, owing to the approach being made by night.

The views of Christiania included the Parliament House, the King's Palace, Karl John's Gade, the Torvet, the Harbour, &c. These sets of slides were succeeded by a very fine series of views illustrating the famous Valdres route, *rid Sandviken*, *Honerfos*, and *Lake Spierlien*.

Those of Fjeldhiem, Vangsmjosen, Smeddal, Borgund, and Haeg, being particularly excellent. The effect of sunrise at Leardalsoren evoked repeated rounds of applause, as also the scenes in the Aardals Fjord, Naro Fjord, and Naro Dal.

Bergen, with its quaint old buildings and busy fish-market, received ample illustration, many characteristic views being depicted.

The concluding pictures gave a good idea of the coast from Bergen to Stavanger, and the subsequent sailing of the Wilson *Eldorado* and its arrival in the Humber (a very cleverly contrived effect) brought a most enjoyable lecture to a close, the lecturer bidding the members adieu with a slide of the Paragon Railway Station, Hull, in the midst of well-merited applause.

The number of pictures shown was one hundred and fifty-six, all of which had been made by Mr. Jacques from negatives taken last year, the lantern plates used being Messrs. Fry's, Mawson's, and Thomas's, and in point of technical excellence and artistic effect left nothing to be desired.

THE STRIPPING OF FILMS FROM GELATINE NEGATIVES FOR PHOTO-MECHANICAL PROCESSES.

The stripping of a negative film when it is in collodion is a comparatively easy matter, but, in the present state of photography, it is quite necessary for one who takes up certain photo-mechanical processes to have a ready means of stripping gelatine films. The descriptions that we have of such processes are, so far as I know, meagre. Wilkinson, for example, in his excellent little book on photo-engraving and photo-lithography, describes methods of stripping collodion negatives only. Such descriptions as I have seen are not generally wrong in principle, they are merely insufficient in detail. Any one taking them up and trying to work from them will find that he is not at once able to strip negatives and get satisfactory films from them, but that he has to work out all the details himself.

The process generally advocated is that of Plener, in which hydrofluoric acid is used to separate the film from the glass. Plener's method is so ingenious, that one is sorry to pour any cold water on it; but, apart from the use of hydrofluoric acid, which every one will avoid who possibly can, it would appear that the etching action of the acid on the glass has nothing to do with the stripping, inasmuch as almost any other acid will act as well as hydrofluoric acid.

This is not an observation made originally by myself, but was, if my memory does not fail me, made by Mr. W. B. Bolton some six months ago. The action, whatever it is, is really the same as the "frilling" of the plate. Although almost any acid that is strong enough, or that has a strong enough action on gelatine, will serve to strip, it is, perhaps, scarcely correct to say that any other acid will do as well as hydrofluoric acid, inasmuch as I have found differences in the

certainty in the action of different acids. After many experiments, I have adopted sulphuric acid as the most certain in its action of any acid, hydrofluoric acid included.

The difficulties that will generally be found in stripping are as follows:—(1.) The films refuse to strip at all. A process which will be quite successful with a negative freshly developed and fixed will often be found not to work at all with a negative that has been treated with alum, and is, say, a year old. (2.) The stripping takes place between the new support and the film, instead of between the film and the glass. (3.) The film after stripping stretches so that, not only is the negative to a larger scale than before—and with a corresponding increase of density—but probably there is likewise distortion, as it is highly improbable that a film will stretch exactly to the same extent in all directions. I saw a complaint of this stretching in one of the photographic journals only a few weeks ago. (4.) The film is so hard and brittle when dry that it cannot be handled without danger of cracking it. And (5.) The film twists or curls in drying, so that it is impossible to get perfect contact between it and a flat surface, such as a collotype film. It has taken me more trouble to ensure getting the film in a perfectly flat and flexible form than has anything else.

If the following directions be precisely carried out, it will be found that any negative, however old, may be stripped with certainty and without encountering any of the difficulties just enumerated. It need scarcely be mentioned that, if the negative has been varnished, the varnish must first be removed by the application of hot methylated spirits.

The following is made up:—

Hard gelatine	2 ounces.
Water	10 "

The gelatine is, of course, soaked in the water till it is soft, when heat is applied. I can recommend Coignet's "Gold Label" gelatine. The solution should be heated to not very far short of the boiling point, and should then be filtered through flannel.

A negative to be stripped is warmed,* accurately levelled, and a certain amount of the gelatine solution is poured on the surface, and is guided with a glass rod till it covers the surface evenly. It is of great importance to measure the quantity, as the ultimate thickness of the film depends on this, and it has to be borne in mind that printing has, if the film is to be used as a reversed negative, to go on through the gelatine.

A quantity of four ounces per square foot will be found suitable for average work. This gives a film, when dry, of about a hundredth part of an inch thick. This sounds very thin, but, in fact, it is a good stout film. The film of an average gelatine dry plate, when dry, is only about one two-thousandth part of an inch thick. Still one-hundredth of an inch will not interfere with ordinary work. For very delicate work the amount of the gelatine solution may be reduced to two ounces per square foot. It is not advisable to use less than this, as otherwise the films will be too delicate for free handling. It is quite possible to flow as much as ten ounces per square foot on glass without any special arrangement for preventing it from overflowing the edges; but a film of the thickness so got is, in my opinion, far too thick for any practical use.

If, however, such a film be wanted for anything, it will be necessary to give four times as long in each solution as is hereinafter directed, as it takes a long time for any liquid to penetrate a very thick film.

A saturated solution of chrome alum is taken, and there is added to it, drop by drop, liquid ammonia, till there is the slightest possible permanent flocculent precipitate. This is merely to neutralise any free acid that there may be, as any such free acid greatly impairs the setting powers of the alum solution.

The gelatine solution having set on the plates, the latter are placed for five minutes in the chrome alum solution. They are then removed and are washed till all the blue colour of the chrome alum has disappeared. They are then placed in a bath of methylated spirit for from half an hour. They are taken from this, the surface is blotted with blotting paper, and they go into a bath of—

Sulphuric acid	1 ounce.
Water	2 pints.

I use ordinary commercial sulphuric acid. I do not know the exact

* I assume here that the negative is one that has been treated originally with alum. If it has not been, it is necessary before the stripping process is begun to treat the negative with alum and allow it to dry, otherwise the hot gelatine solution will probably have the effect of destroying the negative by melting the film. It is particularly necessary to observe this in the case of negatives that have been developed with ferrous oxalate.

specific gravity of it, nor is it of much importance, as a considerable variation in the strength of the bath is permissible.

The following solution is now needed:—

Liquid ammonia	1 ounce.
Glycerine	1 "
Water	2 pints.

The films are left in the sulphuric acid bath till the greasiness caused by the alcohol disappears; this will take about half an hour. At the end of that time, it will be found that the corner of a film may be lifted, and that the whole will leave the glass with the greatest ease. The films go direct from the sulphuric acid bath to that of ammonia and glycerine. The object of the glycerine is to secure flexibility of the films, the object of the ammonia is to neutralise the sulphuric acid. It takes a long time to wash sulphuric acid out of a thick film, and if a long time be given in this case the film will stretch. The small amount of sulphate of ammonia produced in the film by the acid and the ammonia is quite harmless.

Glass is prepared by rubbing the surface with a solution of a few grains of beeswax in each ounce of benzine, and by polishing this away with powdered talc. A film is taken from the last solution as soon as it tastes of acid—no longer, probably in about five minutes; it is placed on a piece of glass, a pad of blotting paper is placed on the back of it, and the squeegee is applied with great vigour. The plate supporting the film is then placed in a fairly warm place, so that the latter may dry; but I find it necessary, after a few hours have elapsed, to paste down the edges with narrow strips of paper and gum solution, otherwise they are sure to rise from the glass before the whole film is dry, and it will be found impossible to get flatness. An attempt must not be made to strip the film from the temporary glass support until it is perfectly dry. Then it is only necessary to insert the thin blade of a knife, when the film will come away in a form in which it is quite handleable, is beautifully flexible, and may be printed from either as a direct or a reversed negative.

It is to be observed that if the film, before it goes into the sulphuric acid, be dried spontaneously in place of by the aid of alcohol, the gelatine support will probably part from the film instead of the film parting from the glass.

The acid bath may, of course, be used for a long time; in fact, as long as it acts. The ammonia and glycerine bath may be used as long as it continues to smell distinctly of ammonia.

I tried drying the stripped films on vulcanite, but found it impossible to prevent them from leaving the surface before they were dry, with the effect that they were hopelessly far from flat.

I fear that the process as I have described it reads as if it were very complicated. It is not really so. A negative may easily be stripped and be drying within two hours of the time of beginning operations, and quite a number may be done at the same time. The drying is the thing that takes longest. With films of average thickness it takes twenty-four hours.

W. K. BURTON.

TRIALS AND TRIBULATIONS OF THE PHOTOGRAPHER.*

THE earliest photographic literature that I remember was *Humphrey's Journal*, and a journal—I think he called it *The Photographic and Fine Art Journal*—by Mr. H. H. Snelling. If there were earlier ones I do not remember them. I have several of the pictures by which they were illustrated after they commenced making photographs, but they are pretty poor things compared to what we make nowadays. Still at that time they were considered wonderful. I well remember the first paper picture I ever saw, and the first little *carte-de-visite* that I ever saw—a friend of mine brought it from Paris. It was a full length picture of a man standing by a fluted column, and his head was a little larger than the head of a pin; and I laughed when I saw it, and I thought it was a very curious little thing; but, however, it was not long before I was making them at the rate of a hundred to a hundred and twenty-five dozen a day.

I have the old photographic publications—a good many of them—and I want to state to you, gentlemen, that this dry plate you are using to-day is the work of care and experience and experimenting almost beyond our reasonable conception. Men have worked with mind and brain for half a century to bring the art of photography to its present status, and they know of the difficulties that were encountered before its success was ultimately obtained, and they can better appreciate its worth than the novice of to-day who finds his apparatus quickly and easily adjusted, his plates and developers all prepared, with printed directions how to use them. In this respect, photography is far different at the present day from what it was in former times. The dry plate, now so universally used, has required an amount of time and labour, discussion and money upon its preparation that one would hardly believe. In its early stages it was thought that it would be desirable for outdoor photography, but the long exposure that was necessary—nearly three times longer than the wet plate—made it doubtful whether it ever would be available. . . .

* Concluded from page 184.

Now I will give you, with your kind permission, a few incidents as they happened day after day. It is a very easy thing to write and talk about photography, but to the man that stands under the skylight it presents a very different attitude. People may not think so, but let them try it. To see thirty and forty different people come up in the course of a day, all different faces—you are expected to make the best view of each face—a face that you never saw before and perhaps never will again, and you are expected intuitively at a moment's notice to make the best picture of that face—it requires an amount of brains that very few have any conception of. And you are asked unreasonable things all the time.

I remember once a lady brought three children, two boys and a girl, to my gallery. They came well armed. The little girl had a doll; there was a hobby-horse brought up; and the other boy had a gun. It was evident that the girl was to hold the doll—that was agreed; but which boy was to ride the hobby-horse? That was to be left to my superior judgment. It was not an easy thing to decide, because both wanted to mount the hobby-horse, and after I had decided it, the mother said she did not want this picture taken like all the "doggertypes" were taken. She wanted the girl in the middle of the room, the boy on the hobby-horse over on the other side of the room, and the boy with the gun on the other side of the room. Well, it was a very brilliant idea, but how my quarter-size camera was going to represent them all, I could not tell, and I told the lady that it was impossible, and I tried to explain to her about the concentration of the light, the lenses, and all that sort of thing, but she did not know anything about that; and she finally said to me that she heard I was supposed to be accommodating, and that she had been to three different places and they all told her what I did, and she did not think that I was any better than any of the rest of them.

One day a Paddy brought in a small case and he said he wanted a life-size picture put into it. It was a difficult thing in those days to make people understand the difference between a full-length and a life-size, and I told him it would not hold a life-size, and then he said, "Well, then, take it with the legs hanging down!"

When General Logan was at my place having a sitting, I remember something that occurred. The General was usually a very reserved man. It was seldom that you could get him to talk, but this time he saw on the walls a man he did not like, and he said to me, "I see that you take anybody's picture." "Oh yes," I said, "that is my business. I don't have time to inquire into a man's private character when he comes here for a picture." "Well," he said, "I suppose you would take the devil if he would sit for a picture." And I said, "Undoubtedly we would;" and I added, "I suppose we could run off a good many down around Washington." "Yes," he said, "that is the place to sell them."

A man came to me one day; he did not like his picture. Oh, how many didn't like them! He said to me, "My picture looks like the devil." "Well," said I, "I could not say, for I never had a sight at that individual; but sometimes a likeness will run all through families."

One morning a lady came into my place, who had two other ladies with her; she ran up to the counter and said, "My picture is twenty years too old, I won't have it, and I want to sit again." The man at the desk passed her right upstairs as soon as possible for another sitting, and as she was passing up, one of the ladies said in an undertone, "Ugly old thing, she looks exactly like it; she only wants to try another dress."

There is another incident that I wish to mention right here before I forget it. It is something that never came under my experience, but I heard of it. The man, in pointing his camera at the sitter, knocked it a little on one side, and instead of having the picture in the middle of the plate he got the man sway off in the corner, and afterwards scolded the man because he did not sit in the middle.

Another old lady came in one day and said she wanted her picture "front face, but a little three-cornered."

I recollect one day two ladies bringing in their mother. A sitting then required thirty seconds. We had a side screen, and after the great deal of preliminaries and the daughters' fixing the old lady's cap in a way that they thought would be the most becoming, I raised the cloth and stepped behind the screen, so that she could not see me, because I did not want to disturb her, and at the expiration of the thirty seconds I emerged from behind the screen and went to the camera and found the old lady looking out of the window.

Here is another one. I wish you could have seen it. A very fine-looking girl came in, with a diminutive specimen of an escort, for a picture, and after I had arranged the position and got my camera all ready, she said to me, "Where must I look?" This little fellow jumped out from behind the screen—he was fully three feet high—and cried out, "Look at me!" and the young lady commenced laughing, and we could not make a sitting of her.

Another time an old lady was in the chair—we set her about thirty seconds, I think; when it was about half over I heard some talking in behind there, looked, and she was motioning with her hands and crying out, "Stop it! stop it! I winked!"

Dr. Tyng—the old gentleman—was sitting one day, and I said to him, "Doctor, I have now made some sittings front face, now I wish you would turn to the left, because I would like to take some side views." And he turned around and said, "Mr. Bogardus, I am an upright man, and I would not turn to the right or to the left for any one."

Then we have had some sad scenes. I remember one day a German woman came in with a bundle and commenced to unroll it, and after she unrolled it I

found it was her dead baby. She brought it there to have a picture taken. So that with all the hilarity, as we call it, we have some sad scenes now and then in the practice of the art.

There was a very singular remark made to me once in my gallery by a judge who was sitting for a picture, and the gentleman who accompanied the judge there that day said, "Now, Judge, look dignified. Look just as you did the last time you sentenced a man to be hanged." And the judge said, "I don't know about that, for that man was reprieved."

But in my experience in the profession I have learned a good many things, and one of the things I have learned is that stout people always want to look thin, and thin people always want to look stout. The older ones don't want the wrinkles to show, and they all want to look a little younger. Many and many a time old ladies have come up to me and would ask me if I could take their picture without showing the wrinkles. "Yes," I would say, "but where will the likeness be?"

A photographer is said not to have any mercy. I remember once a certain judge came with his wife to have a picture taken. The judge was suited with his picture, but when we showed the lady her picture she doubted whether she had quite so many wrinkles; and he straightened himself up and said, "My dear, if you had wanted a handsome one you ought to have commenced thirty years ago." That settled it. I did not have to say another word.

But there were sometimes very laughable scenes in my gallery. I received one time as many as three different letters from a person whom I had never seen; she was a lady; she wanted to sit for a picture. She had been so unfortunate; she had tried here and there to have a satisfactory picture of herself, and they were all "horrid." Well, of course, I had my misgivings about the matter. What the trouble was I could not tell exactly. So I felt very anxious to see her come on the appointed day. A private carriage rolled up to the door and the dressing-maid jumped out and brought all the paraphernalia in. I suppose she weighed at least two hundred and fifty pounds, was gorgeously decked out in a low-necked dress, skin very nearly the colour of a lobster, and was very particular to tell me that she had had so many last ones taken of herself. I made up my mind that, with the material I saw before me, it would be a pretty difficult job to suit her, and so, sure enough, after I took the picture she agreed with me exactly, "that it did look horrid." I did not have to say any more. I never got any pay for my picture.

In conclusion, I would say, young gentlemen, I am glad to meet you. I am glad there are efforts being made to elevate photography, because I have a high idea of it myself, and I believe it is yet undeveloped. The possibilities of photography are still unknown to us. There are more secrets in it than we have ever solved. People think it is about exhausted, but I think there is a future to it, and I think somebody, with patience, study, and experimenting, will bring that future out.

To all interested I say, study well, delve deeply into this great mystery, and some mind will yet evolve from photography results that will cause mankind to look with wonder and astonishment; and, as I have said elsewhere, some name will go ringing down the ages as having added to the pleasures and requisites of a man, and, crowned with the applause of his fellows, his fame shall last as long as time and light continue. ABRAHAM BORDAC.

DAGUERRETYPE.

First operation.—A small phial of olive oil, some finely carded cotton, a muslin bag of finely levigated pumice, a phial of nitric acid diluted in the proportion of one part of acid to sixteen parts of water, are required for this operation. The operator must also provide himself with a small spirit lamp and an iron wire frame, upon which the plate is to be placed whilst being heated over the lamp. The plate being first powdered over with pumice by shaking the bag, a piece of cotton dipped into the olive oil is then carefully rubbed over it with a continuous circular motion, commencing from the centre. When the plate is well polished it must be cleaned by powdering it all over with pumice and then rubbing it with dry cotton, always rounding and crossing the strokes, it being impossible to obtain a true surface by any other motion of the hand. The surface of the plate is now rubbed all over with a pledget of cotton slightly wetted with the diluted nitric acid. Frequently change the cotton and keep rubbing briskly, that the acid may be equally diffused over the silver, for if it is permitted to run into drops it stains the table. It will be seen when the acid had been properly diffused from the appearance of a thin film equally spread over the surface. It is then to be cleaned off with a little pumice and dry cotton. The plate is now placed on the wire frame, the silver upwards, and the spirit lamp held in the hand and moved about below it so that the flame plays upon the copper. This is continued for five minutes, when a white coating is formed all over the surface of the silver, the lamp is then withdrawn. A charcoal fire may be used instead of the lamp. The plate is now cooled suddenly by placing it on a mass of metal or a stone floor. When perfectly cold it is again polished with dry cotton and pumice. It is necessary that acid be again applied two or three times in the manner before directed, the dry pumice being powdered over the plate each time and polished off gently with dry cotton. Care must be taken not to breathe upon the plate or touch it with the fingers, for the slightest stain upon the surface will be a defect in the drawing. It is indispensable that the last operation with the acid be performed immediately before it is intended for use. Let every particle of dust be removed by cleaning all the edges and the back also with cotton. After the first polishing, the plate is fixed on a board by means of four fillets of plated copper; to each of these are soldered two small projecting pieces which hold the tablet near the corners, and the whole is retained in a proper position by means of screws.

Second operation.—It is necessary for this operation, which is really the most important of all, that a box be provided, hereafter called the saline box; that is, the box

in which the plate is iodised. To prepare the plate, the cover being taken out, the cup is charged with a sufficient quantity of iodine broken into small pieces and covered with the gauze. The board is now, with the plate attached, placed face downwards in its proper position and the box carefully closed. In this position the plate remains until the vapour of the iodine has produced a definite yellow colour, nothing more nor less. If the operation is prolonged beyond the point at which this effect is produced a violet colour is assumed, which is much less sensitive to light; and if the yellow coating is too pale the picture produced will prove very faint in all its parts. The time for this cannot be fixed, as it depends entirely on the temperature of the surrounding air. No artificial heat must be applied, unless in the case of elevating the temperature of an apartment in which the operation may be going on. It is also important that the temperature of the inside of the box should be the same as it is without, as otherwise a deposition of moisture is liable to take place over the surface of the plate. It is well to leave a portion of iodine always in the box, for as it is slowly evaporised it is absorbed by the wool, and when required it is given out over the more extended surface more equally and with greater rapidity. According to the season of the year, the time for producing the required effect may vary from five minutes to half an hour or more; it is therefore necessary from time to time to inspect the plate. This is also necessary to see if the iodine is acting equally on every part of the silver, as it sometimes happens that the colour is sooner produced on one side than on the other, and the plate, when such is the case, must be turned one quarter round. The plate must be inspected in a darkened room to which a faint light is admitted in some indirect way, as by a door a little open. The board being lifted from the box with both hands, the operator, turning the plate towards him rapidly, observes the colour. If too pale it must be returned to the box, but if it has assumed the violet colour it is useless, and the whole process must be again gone through. From description this operation may appear very difficult, but with a little practice the precise interval necessary to produce the best effect is pretty easily guessed at. When the proper yellow colour is produced the plate must be put into a frame which fits the camera obscura, and the doors are instantly closed upon it to prevent the access of light. The third operation should, if possible, immediately succeed the second; the longest interval between them should not exceed an hour, as the iodine and silver lose their requisite photographic properties. It is necessary to observe that the iodine must never be touched with the fingers, as we are very liable to injure the plate by touching it with the hands thus stained.

Third operation.—The third operation is the fixing of the plate at the proper focal distance from the lens of the camera obscura and placing the camera itself in the right position for taking the view we desire. This instrument reverses the objects—that which is to the right in nature being to the left in the photograph. This can be remedied by using a mirror outside. It is at an angle of 45°. This arrangement, however, reduces the quantity of light and increases the time of operation one-third. After having placed the camera in front of the landscape or any object of which we desire the representation, our first attention must be to adjust the plate at such a distance from the lens that a neat and sharply defined picture is produced. The adjustment being satisfactorily made, the glass is removed and its place supplied by the frame containing the prepared plate. The length of time necessary for the production of the best effect, varying with the quantity of light, is a matter which requires the exercise of considerable judgment. At Paris this varies from three to thirty minutes. It is very important that the time necessary is not exceeded. Prolonged solarisation has the effect of blackening the plate, and this destroys the clearness of the design.

Fourth operation.—The apparatus required for this operation is a box as sketch shows. The board and the fixed plate being withdrawn from the camera are placed at an angle of 45° within this box, the tablet with the picture downwards, so that it may be seen through the glass. The box being carefully closed, the spirit lamp is to be lighted and placed under the cup containing the mercury. The heat is to be applied until the thermometer, the bulb of which is covered with mercury, indicates a temperature of 60° Cent. (140° Fahr.). The lamp is then withdrawn, and if the thermometer has risen rapidly it will continue to rise without the aid of the lamp, but the elevation ought not to be allowed to exceed 75° Cent. (167° Fahr.). After a few minutes the image of nature impressed, but till now invisible, on the plate begins to appear. The operator assures himself of the progress of this development by examining the picture through the glass by a taper, taking care that the rays do not fall too strongly on the plate and injure the nascent image. The operation is continued till the thermometer sinks to 45° Cent. (113° Fahr.). When the objects have been strongly illuminated, or when the plate has been kept in the camera too long, it will be found that this operation is completed before the thermometer has fallen to 55° Cent. (131° Fahr.). This is, however, always known by observing the image through the glass.

Fifth operation.—This process has for its object the removal of the iodine from the plate of silver, which prevents the further action of the light. A saturated solution of common salt may be used for this purpose, but it does not answer nearly so well as a weak solution of hyposulphite of soda. In the first place, the plate is to be placed in a trough of water, plunging and withdrawing it immediately, it is then to be plunged into one of the saline solutions, which would act upon the drawing if it was not previously hardened by washing in water. To assist the effect of the saline washes, the plate must be moved to and fro, which is best done by passing a wire beneath the plate. When the yellow colour has quite disappeared the plate is lifted out, great care being taken that the impression is not touched, and it is again plunged into water. A vessel of warm distilled water, or very pure rain water, boiled and cooled, being provided, the plate is fixed on an inclined plane and the water is poured in a continuous stream over the picture. The drops of water which may remain upon the plate must be removed by forcibly blowing upon it, for otherwise in drying they would leave stains on the drawings. This finishes the drawing, and it only remains to preserve the silver from tarnishing and from dust.

The shadows in the Daguerreotype pictures are represented by the polished surface of the silver, and the lights by the adhering mercury, which will not bear the slightest rubbing. To preserve these sketches, they must be placed in cases of pasteboard with a glass over them, and then framed in wood. They are now unalterable by the sun's light.

These constitute the substance of the directions given by M. Daguerre in his pamphlet and patent specification. The process was, however, much simplified and shortened, the enormous expense of the original apparatus having been found quite unnecessary.

Should any one possess a Daguerreotype which may have become tarnished, they should carefully remove the plate from the mount and pass a camel's-hair brush lightly over the surface, then pour over two or three times from a measure some alcohol; now plunge the plate into a cyanide solution (of fifteen grains to the ounce of distilled

water) and rock it until all the tarnish has disappeared and the plate looks bright. This may take from three to six or seven minutes. The plate must now be well washed in clean water, and finally with distilled water, and dried in the following manner:—Hold the corner by a pair of pliers and with a spirit lamp warm the back of the plate, at the same time blowing with the breath, without stopping, until the surface is dry. If care has been taken the picture will be as bright as on the day it was taken. Every care must be taken not to touch the surface except with a camel-hair brush should dusting be necessary. Great care must be taken in remounting the Daguerreotype; it must be bound round with this gummy paper, to prevent the air getting in between the plate and the glass, or it will soon show signs of tarnishing; if well done it will have secured it a new lease of existence.

Simultaneously with the discovery by Nicéphore and Daguerre in France, our own countryman, Mr. Fox Talbot, had perfected researches upon which he had been engaged in the same direction since 1835, and the result was in 1839 made known by him, under the name of photographic drawing, and which he perfected in 1842 under the title of the Talbotype or calotype. This process differed from Daguerre's, inasmuch as it was on paper, and the picture being negative, that is with the lights and shadows reversed, it possessed the power of a plate from which an unlimited number of positive proofs might be printed, the diaphanous texture of the paper used allowing the passage of sufficient light. But this process had likewise its disadvantages, although they were in another direction; it was rather too slow in receiving the action of light to be applied to portraiture and the life, and was deficient in fineness and delicacy of execution when landscape, architecture, and still-life were treated by it.

Fox Talbot was certainly the first to publish his process. But it was proved at a trial, Talbot *versus* Laroche, in 1854 that the collodion process invented by Mr. Scott Archer was no infringement of the calotype process, and that the Rev. Mr. Beadle, vicar of Stoue, near Aylesbury, had practised a similar method to that of Mr. Talbot as early as 1837.

Fox Talbot patented every process he practised, and intended to renew his patent, he having applied for a renewal when he entered an action against Laroche for infringement of his patent. The trial took place at the Guildhall, London, before Lord Chief Justice Jervis and a special jury, and lasted three days, when Laroche was found not guilty of infringement. Fox Talbot's patents were consequently upset; the result of the trial, therefore, being that photography was thrown open to the world for any one and every one to practise it.

In conclusion, I may say that the large specimens of Daguerreotypes I have brought for you to see to-night are the work of Silvestre Laroche, the photographer before mentioned in the trial with Fox Talbot. He took a medal in the Exhibition of 1851 for Daguerreotype pictures, some of these being among them. He had the honour of taking several portraits of Her Majesty the Queen; he photographed the whole of the interior of Hampton Court Palace, copies of which Her Majesty, the Prince Consort, and other members of the Royal Family took sets. Also a series of the late Mr. and Mrs. Charles Keen in several of their historical plays at the Princess's Theatre, London, including his Macbeth. He was also an ardent worker in the laboratory of Scott Archer at the time he discovered collodion.

W. THOMAS HORTON.

TWENTY YEARS OF AMATEUR PHOTOGRAPHY.

(A Communication to the Dundee and East of Scotland Photographic Association.)

A ~~mere~~ recital of the ups and downs of an amateur's photographic experience for either a long or a short period would scarcely command your attention. An historical account of the processes introduced and forgotten would scarcely be much better, and yet I think I myself would have been thankful had any one, fifteen years ago, pointed out to me a few of the many things I have learnt by bitter experience since.

It is my intention to refer to a few matters photographic, having little connexion the one with the other, and yet all of them interesting enough, I hope, to take up a little of the Society's time. Comparing the past with the present, there is one point which strikes me somewhat painfully. I may be mistaken, but I am under the impression that twenty years ago there was a bond of sympathy between all who practised the black art that there is not now; amateur and professional fraternised with each other, and exchanged items of experience in a very friendly way. There was no mention or hint then that amateurs were taking the bread from the professional, or that they were amusing themselves in any but a perfectly legitimate way.

However the feeling comes about, or whoever is to blame, there can be no doubt that amateur and professional are drifting apart, and that jealousies are springing up which ought not to be. I know that there are exceptions, and our worthy President is one of them, but, after some consideration of this matter, I am convinced that for some reason professional photographers do as a rule look with somewhat of suspicion on the modern amateur. But some one may say, is this to be deplored? What can the professional do for the well-read and perhaps scientific amateur? may he not be allowed to sulk as he likes—who cares? Provided the amateur has done nothing unworthy to bring this about, certainly he may; but, and here comes the whole reason for the introduction of such a subject, are amateurs always careful enough in recollecting precisely what an amateur is? I am sure that not one of us would willingly take the bite from any man's mouth, but I know, not one, but a few, who, out of sheer want of consideration, undertake work which is purely in the province of the professional. When this is pointed out, the answer sometimes is: All that ever I got for my photographs would scarcely cover the expense of my kit. But it should be remembered that to the extent of their remuneration they are not amateurs but professionals. An amateur is one who pursues a certain pastime or study purely for the love of it and in no case for payment, especially in money. Amateurs in every profession or sport are in honour bound to live and let live, and should never be the means of diverting one single penny from their professional brethren, who of course have to earn a livelihood by their work. It is sometimes said that amateurs are thriving off the brains of the professionals. This I do not go in with at all. The history of photography quite plainly shows that amateurs have generally been the pioneers in discovery, and, indeed, if you run over in your minds the great names in the photographic world, not only now, but since the earliest discovery in connexion with the subject, you will find very few professional photographers amongst them. It is certainly not on the score that amateurs have done nothing for photography that I would have them to keep carefully the amateur status, but simply because it is an ungenerous thing to so ride a hobby to the injury of an honourable and obliging profession. My idea is that an amateur may photograph where and what he chooses, and

he is also entitled to preserve his pictures in any form he likes, framed, if he likes, by himself, but there I would have him stop. It may be over particular, but I scarcely think he is entitled to print a single copy to give away, for then he diverts a possible customer from his professional brother, and this, I think, is not fair. I have a right and invariably do print a copy for myself, but for some years now have always had a professional to print prints which I wished to give away, and this, I think, is the only fair way to do.

These views may give rise to discussion, but so much the better if they do, and I shall try to defend my points by arguments at greater length than are possible in a short paper.

CHAPTER II.

There are generally three stages in an amateur's photographic life; there were at least three in mine. The first stage is when the tyro, knowing no better, attempts everything, and much to the surprise of the experienced, produces, at rare intervals, real pictures. It is quite true that he himself is not aware of the fact, and generally looks upon these accidental gems as his worst productions. At this stage quantity is the word. He exposes two dozen of plates in a day's outing, and when he has developed them all and found three-fourths of them which even he has to apologise for, he nevertheless religiously prints half a dozen copies from good and bad alike, and sits up half the night mounting this huge batch, to the intense disgust of the entire family, who anathematise him as he mounts the creaking stairs to bed, cold and shivering. At first he hordes these paltry things, but as he gets into the way of toning and fixing, &c., he becomes lavish and gives them away freely. It is generally at this stage, too, that the amateur begins an album, a record of his progress, and to be continued, perhaps, for a lifetime. He prints a batch of about nine (very carefully) and mounts them in the book. As he climbs into higher regions, however, he looks back upon the first fruits of his prentice hand and wishes he had delayed the commencement of his album. From this moment the book is doomed. What a week ago was to be a life's record is tossed into a press and forgotten; no, not forgotten, for one's sisters and his cousins and his aunts constantly demand to see what has been added since they last saw the book, and it requires a most experienced romancer to find a good and sufficient excuse every time they call.

The second stage is associated with very different symptoms. The amateur has now grown experienced, his terrible productions have scared him, and now in place of risking a plate upon anything and everything he can never get all the circumstances just what he would like. In the morning there is a haze which almost makes him hypochondriacal; at midday there is a puff of wind which makes him say bad words, while in the evening the sun either shines into his lens or, if he turns the other way, his giant shadow disfigures the foreground of his picture.

It is at this stage that he gets a bigger camera; at this stage he also makes his own plates at fourpence a-dozen, at least so he says—generally too rapid and good for getting pictures on however. It is now that he begins to discover that he cannot get good tones in his prints. While in church he connects in his mind's eye a toning bath to be tried to-morrow, if he can wait so long; if not, then as soon as possible. He has by this time been introduced to some professional photographer, and pesters his very life out over mysterious spots on his plates or his prints. He carries a negative or two in his pocket, and always half a dozen prints, generally portraits badly retouched (for he has commenced that), and asks you for your honest opinion. Things begin to look serious at home, too. It is on the parental side an open secret that you are spending by far too much, both time and money, on that trash; sisters begin to refuse to sit to you, and negatives which have been left to dry have been carefully dusted for you on the film side with a ragged duster.

Worry, care, and anxiety are beginning to tell. In an evil moment he had taken his whole-plate camera to a picnic, and having exposed half a dozen plates in six different ways, all of them good, he finds that he has promised no fewer than a hundred and five prints, work to occupy every spare moment for the rest of the summer. Things look bad; he neglects everything and everybody for the cursed infatuation. The very sanctuary he cannot get to, and at last his conscience awakens to its lost condition. Then it is that the third stage begins.

This is something reasonable at last. Our amateur now discovers that a little mist or haze in the distance may soften the harsh outline of a far-away hill. He can wait with patience for a quiet moment when a little wind is blowing, nor does he imagine that every blade of grass must be stock still or his picture is ruined. In the evening, when the sun is low, he brings forth his camera—not puts it away—and secures the lovely sunset and the quiet village. He throws aside his whole-plate camera as being a toil rather than a pleasure, and takes to a light and simple 5×4, or even less.

The plates are good and cheap to buy this size, and he ceases to make his own, and consequently gets to bed with other people. He does not bother his head about toning baths, but either makes at his leisure a lantern slide, infinitely to be preferred to any print, or should he wish to present a print, asks his professional friend to do him a couple—done well and for little money. He returns to Christian habits, and actually can follow the sermon once more in church.

These are the three stages. I congratulate myself at having arrived at the third, and pity from the bottom of my heart those who are at the first, or even more so at the second.

CHAPTER III.

I have already said that I have arrived at that stage where a light and simple outfit is a *sine qua non*, and I think that this idea would stand a little amplification. I often wonder what those gentlemen who work large-sized plates do with the pictures after they have got them. As a rule, a print is printed and pasted into an album. If it is on albumenised paper, in a dozen years symptoms of fading will have very likely begun, and just as time wears on and the interest increases in the picture, it gets yellower and yellower till for very shame the book is produced no more. Prints in platinum are permanent and very beautiful, but if a picture is to be held in the hand when looked at it need not be of large size, while if it is to be framed and hung, a 10×12 photograph is even too small for decorative purposes. My argument is, that from the fineness of detail of a photograph it must either be looked at in the hand, or, if hung on the wall, it must be very large, say 20×30, before any good effect can be produced by it. A water or oil colour is quite a different thing, and suppression of detail so gives breadth of effect that size for size they are doubly effective compared with photographs.

Those who have nothing else to do but amuse themselves might well take to a size of 20×30 direct pictures. Paper coated and stretched upon light frames would be quite workable, and the results would certainly be worth all the trouble to get them. But for those who can snatch a day only now and again, they should adopt no middle

size—too big for the hand, too little for the wall—but adopt the handiest and simplest they can get and be content with lantern slides. It may be argued that to set up a lantern and screen each time the pictures are to be looked at is very troublesome; but transparencies are very beautiful, even looked at in the hand, while they have the additional advantage of being suitable for the lantern if required. A carefully made slide is practically indestructible with ordinary care, and should a silver or platinum print be required at any time, a negative of any size can be made with a minimum of trouble from the transparency.

CHAPTER IV.

Developers.—A very elaborate series of experiments last summer with soda and ammonia, tried critically the one against the other, brought me some interesting information. I found, for instance, that while soda developed a plate to perfection, if to be used for printing on albumenized paper, ammonia made a far superior developer for a negative to produce a transparency from. Soda seems to pile up density at the expense of detail, which gives a grand printing negative, but which produces a transparency lacking in fineness and detail. Soda gives greater latitude in exposure, indeed the exposure, within reasonable limits, may be anything, and this is a great boon; but since all my negatives are now to be for lantern slides only, I intend to give up soda and keep by ammonia.

CHAPTER V.

Lenses.—After due consideration it seems to me a difficult thing to understand where makers get in the high prices for lenses. Why, for instance, should a lens of six-inch focus be about half the price of a lens of twelve-inch focus, the diameter remaining the same? The mere difference in the curves cannot make this difference in the cost of production. The fact that it covers a larger plate is an accident of its form and in no way due to finer workmanship on the part of the manufacturer. In portrait lenses there might be some excuse for higher prices, for here the diameter of the lens is so great that the getting even of flawless glass in sufficient sized discs is something. The introduction of the rapid gelatine processes has had this advantage, that cheap lenses may be used and give as good results as higher priced instruments. I shall show, by means of the lantern, pictures taken with lenses ranging in price from 1s. to 50s. in which the definition is equally good in the cheap as in the dear. When it was necessary to work with as great an aperture ratio as possible, then truly fine lenses were necessary, but when apertures of one-sixteenth to one-sixty-fourth became the general rule, the necessity for fine lenses, or any lenses at all for that matter, is not so evident.

To have no lenses at all is more a theoretical curiosity than anything else, but very good pictures may be produced without any lens, and that with by no means a very prolonged exposure with our rapid plates. The principle of the thing remains, that as the aperture ratio gets less and less the lens has less to do, and consequently need not be so perfect an instrument. In other words, whatever the fault of a lens, stopping it down will cure or mitigate it, and in every case give enhanced definition. A lens not quite correctly achromatic will not be improved in this respect by stopping down; but this is an extremely rare fault, even in the cheapest of lenses.

This then is an experience of mine, that in the great majority of instances more money is spent on a lens or lenses than is necessary, even when the very finest work has to be done. Of course, makers insist that to do fine work very expensive lenses are necessary. Experience, however, proves the contrary. I have never been able to see where the advantage came in using the rapid rectilinear type of lens unless where a very wide angle had to be included with straight lines at the margin. I find that the most of half-plate rectilinears, for instance, have an equivalent focus of nine inches. Now a nine-inch single lens will be quite rectilinear on a half-plate, and as to aperture, it will work very well at $f/12$, which is as rapid as is necessary for instantaneous work, and, indeed, has greater depth of focus than a rectilinear working with a slightly larger aperture. Where a half-plate has to be covered with a three and a half inch focus lens a double combination becomes a necessity—otherwise distortion.

Cameras.—I have found nothing to equal the sleeve camera, especially for plates up to $6\frac{1}{2} \times 4\frac{1}{2}$. Its advantages are its simplicity, little bulk, perfectly light-tight, and the great number of plates which may be carried and changed in it. I will show the working of this camera.

Pictorial Effect.—As a rule, by far too much attention is paid to the purely photographic part and too little to the artistic. So much am I personally convinced of this that I would have all photographic competition pictures to be judged by no other standard than their artistic value, and to that end would appoint judges who knew good pictures but were quite ignorant of photography. The end and aim of photography is to make pictures, not mere mechanical copies of objects, however perfect. Nothing could certainly be more absurd than the method taken by this Society to judge the lantern slides, for, assuming that we are none of us perfect (which is putting it mildly), since the award is the average of the members, with very different tastes and ideas, it is simply a case of the blind leading the blind, and the result must always be that the mediocre set will come out first. This result is brought about in this way. Assume for a moment that every member of the Society has his own special quantum of artistic knowledge, and that, as is most likely, no two members have exactly the same quantum. It follows from this that a slide not too much above Dick and not too much below Harry will take the first place, for it will get votes from both, although in point of fact it is not actually the best slide. But leaving this aside, where does the educational value come in if a whole class agree to correct each other's exercises? Mainly the best scholar is howled down by the majority whether he be right or wrong. Who need compete at our lantern competitions when he knows nothing whatever of his neighbour's judging powers? The Society is wealthy, why not pay to have the services of an artist to judge our productions, one whose judgment would be welcomed by every member, and trusted? One would then compete, and, successful or unsuccessful, he would learn from an undoubted authority either how to do it or how not to do it.

If technical excellence is to be taken into account, then let there be two judges and two prizes—one for artistic excellence and one for technical excellence, any attempt to strike a balance between sets, taking both qualities into account, being simply ridiculous, as any one will admit who has ever tried the experiment. Listen to the remarks, for instance, over some prize photographic picture; can you ever get two to agree as to its precise value? One man judges it from a purely technical point of view because he knows nothing about the artistic; another judges it from its value as a picture and sinks its technical imperfections, or, at least, judges them less harshly. These two are diametrically opposed to each other and are quite incompatible with each other, therefore never can be found in one man. Undoubtedly the best plan is to have our productions judged as pictures, set up no standard of technical excellence, but let the judge be purely an artist, indifferent as to whether they are good or bad

from a photographic point of view, but saying with no uncertain voice whether or no they contain the subtle something which measures the mind that conceived them. It must be remembered that pictorial value appeals to every one, while photographic value is only evident to photographers.

While upon this subject I cannot help mentioning that three handbooks, entitled—Green's first, second, and third parts—*Sketching from Nature*, have proved of great value to myself, and as the price is only half-a-crown for the three I cannot do better than advise the small sum to be invested in them.

Orthochromatic Photography.—I have exposed a good many plates supposed to be orthochromatic, both home made and bought, but cannot say that I knew much difference in the result. I shall show a few slides, the negatives for which were made from plates deeply stained with turmeric yellow, home made. I also used at the same time a yellow screen in front of the lens diaphragm. The advantages from orthochromatic plates were not sufficiently striking to induce me to continue their use.

The Flash Light.—Notwithstanding the drums and trumpet with which the advent of this invention was heralded, I myself have got no satisfactory results from it. The light and shade of a portrait must be studied carefully before exposure of the plate, and this is, of course, impossible with the flash light. I shall show a slide of my most successful flash light portrait, always admitting that chance helped largely in the result.

PATENTS COMPLETED.

A POCKET SUPPORT FOR PHOTOGRAPHIC CAMERAS.

No. 5096. GEORGE LOWDOX, 65, Reform-street, Dundee.—*April 17, 1888.*
To provide a portable apparatus as a means of fixing photographic cameras to trees, palings, sides of ships, &c.

This apparatus is constructed of two pieces of wood or other material, of small size, hinged together at the end so that by attaching one of the pieces by means of a thumbscrew, armed with a self-inserting screw, to a tree or other standing support, the other hinged-on part may be brought down to right angles, or any angle required, more or less. On this lowered part is attached the camera. To strengthen and support the camera, and to adjust its position more accurately, I have a dovetailed slide in the one part, preferably the upper. This slide is again hinged, and by being pushed in, in the said dovetail, is lowered and attached to the lower, or fixed part, and so acts as an adjustable bracket or support—when the weight of the camera is upon it.

MEASURING THE SPEED OR TIME OF EXPOSURE OF PHOTOGRAPHIC INSTANTANEOUS SHUTTERS.

No. 5755. WILLIAM JOHN WILSON, 1, Chapel-road, Ealing, Middlesex.—*April 18, 1888.*

To carry out my invention I use a sheet of glass or other transparent or translucent material, upon which are marked one hundred or other convenient number of dots, lines, or other divisional marks, arranged in a circle and at equal distances apart. This plate marked with the graduated circle may be made of translucent material, the divisional marks being opaque, as above described, or the plates may be opaque and the divisional marks translucent. For instance, in the latter case the plate may be made of metal, and the divisional marks holes through which the light can pass. The graduated circle plate being fixed in an upright position, an opaque circular disc, a little larger than the graduated circle, is placed parallel and very close to, and concentric with, the graduated circle. The opaque disc is perforated with a radial slot, the width of which is the same as that of one division on the graduated circle, and the disc is arranged so that it may be caused to revolve on its centre at any required speed. It will now be understood that if the graduated circle plate be illuminated from the back, and the disc be caused to slowly revolve, the divisions on the circle will become visible, one at a time and in succession, to an observer standing in front of the revolving disc. In order to measure the speed of a shutter I set the disc in motion and keep it revolving at a uniform rate, say, for example, once in each second. I strongly illuminate the graduated circle plate from behind with sunlight, electric light, the light of burning magnesium, or other sufficiently powerful illuminant, and then, using the shutter to be tested with a lens and camera in the usual way, I photograph as much of the graduated circle as becomes visible through the revolving slot during the action of the shutter. If the time of the revolution of the disc is greater than the time of exposure of the shutter, the latter is shown by the number of divisions which appear in the resulting photograph. For example, if the circle be divided into one hundred parts, and the disc be revolving at the

rate of twice per second, and twenty-five divisions appear in the photograph, then the time of exposure of the shutter is evidently twenty-five two-hundredths, or one-eighth of a second.

AN IMPROVED PHOTOGRAPHIC SHUTTER.

No. 12, 174. LOUIS HOUSSARD, 5, Wilmington-square, Clerkenwell, W.C.
—August 30, 1888.

An improved shutter for photographic cameras, being an improvement in quickness and regulation of speed of exposure, also being shakeless in action. The shutter is composed of a thin brass box of rectilinear form, an aperture being in the centre. Inside of the box are two sliding plates which open from centre of the aperture in opposite directions. The aperture of the sliding plate can be made to open round, oval, or square. At the bottom to the left of the box is a small divided wheel for regulating the speed of exposure. On the right-hand side of the box is fitted pneumatic and hand release, also a focussing lever; the shutter can be fitted on hood or between lens.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
March 23	North Middlesex Club	The Iron Room, Stroud Green.
"	Great Britain (Technical)	5A, Pall Mall East.
"	Bolton Club	The Studio, Chancery-lane, Bolton.
"	Photographic Club	Anderson's Hotel, Fleet-street, E.C.
"	Barton-on-Trent	The Institute, Union-street.

"	Oldham	The Lyceum, Union-st., Oldham.
"	London and Provincial	Masous Hall Tavern, Basinghall-st.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

MARCH 14.—Mr. F. W. Cox in the chair.

Mr. F. A. Bridge exhibited an enlargement on pink bromide paper, but it was not considered to possess any advantage over white paper.

Mr. A. HADDON remarked that pink paper was manufactured by a firm in France, and inquired whether the sample before them came from that source. Mr. BRIDGE believed that it did.

The CHAIRMAN submitted a negative which had become yellow and asked the best means of intensifying it.

Mr. J. TRAILL TAYLOR thought it required clearing only in order to print well.

Mr. F. C. Kellow was elected a member of the Association.

Mr. T. E. Freshwater landed round a number of bromide and silver prints of views in India, also two small bronze gods.

The CHAIRMAN announced that the question box contained a query to the following effect:—"It having been stated that the best form of condenser for using with an oil light was not considered the most applicable for use with a limelight, what were those best adapted for the purpose?" and suggested that the question be allowed to stand over until the next meeting.

On a former occasion it having been decided that members make lantern transparencies from the same three negatives and submit them for competition, the products were exhibited by means of the lantern, two pictures at a time being projected side by side upon the screen, the better one—which was decided by vote—to remain upon the screen and the other withdrawn, and in its place substituted another, and so on, the last one remaining in view being that which had been voted to take the first place. The first place in all three cases was awarded to Mr. J. R. B. Wellington, two of his pictures being on gelatine and one on a bromide plate. The second places were awarded, one to Mr. H. M. Hastings—a gelatine plate, and two to Mr. Cooke for collodion and gelatine respectively.

Mr. FRESHWATER then exhibited, by means of the lantern, a number of views to which he had previously referred, and gave a description of each—these illustrating the manners and customs of some parts of India.

The HON. SECRETARY announced the third annual Conference of the Camera Club, to be held on March 27 and 28.

At the next meeting of the Association Mr. F. P. Cembrano will speak upon *The Novelties at the Crystal Palace Exhibition*.

CAMERA CLUB.

At the lantern evening on March 14 a very large number of slides were exhibited on the screen. The photographs shown included the work of the winners in Messrs. Fry & Co.'s recent lantern slide competition, also slides toned with gold, by Mr. O. F. Blackmore; experimental work upon rapid and slow chloride plates, by Mr. J. D. England, showing the range of colour obtainable; flower studies and groups, by Mr. Henry Stevens; photo-micrographs, by Mr. Charters White; interiors at Sandringham, the slides by Major Nott, from negatives of Mr. Lemeray's; collodio-bromide work, by Mr. Hussey; and general landscape scenes, by Messrs. Fluney, Noel-Cox, Ferrero, Seyd, Howlett, Leventhorpe, Elder, Rodgers, Lanrie, Fitzpayne, Gladstone, Grinshaw, Wilkison, and the Hon. A. W. Friskine.

On March 28, the Thursday of Conference week, novelties in apparatus will be shown at the Club and explained by the exhibitors.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

THE Committee of this Association met on the 15th instant at 181, Aldersgate-street, E.C.

The minutes of the previous meeting, having been read, were confirmed.

Acting upon the resolution carried at the general meeting, steps were taken towards the settlement of the proposed Orphans' Fund, also the initial stages of a complete revision of the rules of the Association.

It was decided that an additional 100% of the funds be invested in Goschen's Two and three quarter-Per Cent. Consols.

Messrs. F. W. Cox, G. T. Harris, and E. A. Whittemore were elected members of the Committee.

HOLBORN CAMERA CLUB.

At the headquarters, 100, High Holborn, on Friday last, the HON. SECRETARY explained to beginners in photography *How to Use a Camera and Photographic Lens*, and on Friday, April 19, he will deal with *The Correct Exposure and Best Means of Developing Plates*.

The President (Mr. W. Rice) has promised a series of papers on *Technical Tricks*, the first of which will be commenced soon after the annual general meeting on April 5, and will be on the subject of *Diaphragms*.

In addition to a new set of rules, which will be submitted to the members at the annual general meeting, the Committee will suggest an extensive programme for the coming season. All who think of becoming members should send a line to the Hon. Secretary before that date so that they may have a voice in the future management of the Club.

Messrs. E. H. Bayston, John Brittain, and Frederick Knights were elected members.

SHAFTESBURY PHOTOGRAPHIC SOCIAL.

MARCH 15.—the monthly lantern evening.—Mr. Tollett in the chair.

Mr. J. B. RINTOUL read a paper entitled *In and Round London*, illustrated with dissolving views. About sixty slides were exhibited.

WEST KENT AMATEUR PHOTOGRAPHIC SOCIETY.

MARCH 8.—Mr. Pringle presided.

Mr. Hawkins showed two prints from negatives of highly coloured engravings. They were taken on ordinary plates, and, notwithstanding this, the range of colours was well represented by an equally good range of tone in the finished print. The room in which they were taken was lighted with yellow light. It was remarked that if such good results could be obtained by such simple means, orthochromatic plates would not be required for such subjects. Mr. Hawkins also contributed a print to the album.

Mr. Sanderson brought some lantern slides for criticism, some of which were curiously marked in spots and patches. These were apparently caused by the hypo not being eliminated, or by some splashing after they were washed.

Mr. CHARLES HUSSEY then proceeded to deliver an address upon *Lantern Slide Making*. The lecturer said that he was in the habit of using a small camera, most of his slides being printed by contact; he also found that his negatives would produce pictures of sufficient dimensions when enlarged from to suit the most exacting on that score. To illustrate this, he handed round a three and a quarter negative and three enlargements from it, the largest being about 30 x 22. The original negative being sharp and full of detail, the enlargements were perfect, the largest being equally good with the smallest. Mr. Hussey next handed round two cameras, a quarter-plate and a three and a quarter square. The camera was made of long extension, so that lenses of varying focal could be used. At least four lenses should be carried, one being a wide angle, which, however, should only be used when absolutely compelled to do so. Here is a valuable hint as to the use of the camera as a view meter:—Place your eye to lens hole in front of camera (having previously removed focussing screen) and rack out the camera until the subject just fills up the view, then choose a lens of corresponding focus. He also showed a few examples of negatives. Comparing the two processes, gelatine and dry collodion, the lecturer expressed his opinion in favour of the latter, as with it one is enabled to give any tone to the transparency that may be desired after the development has been completed; with the gelatine process this cannot be done. A number of slides and negatives were shown at the conclusion of the address.

The next meeting will be held on the 22nd instant, on which occasion the Secretary, Mr. E. G. Adams, will give an address upon *Warm Tones on Gelatine Lantern Slides*.

BRIGHTON PHOTOGRAPHIC SOCIETY

FIRST lantern evening, March 12, at the New-road Lecture Hall. There was large attendance of members and their friends.

Upwards of one hundred slides were exhibited and were warmly applauded.

Mr. Harcastle sent a dozen by Messrs. Fry & Co.; Mr. Rean showed one of the moon and others; Mr. Webbing, a varied assortment and one of the ill-fated *Vandalia*, now a wreck off Brighton; Mr. Tate, miscellaneous views; Mr. Jago, portraits; Mr. P. Morris, local views round Lewes; and the Hon. Secretary (Mr. Corder), views in and round Canterbury and local subjects.

It was decided that at the next meeting, on March 26, the subject for discussion should be *Lantern Slide Making*.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

MARCH 14.—Dr. Hill Norris (President) in the chair.

A letter was read from Mr. A. Tate, of the Ulster Society, informing the Hon. Secretary that he had sent off a selection of slides of Irish scenery for exhibition.

Bound copies of the annual ALMANAC were handed in from the editor of THE BRITISH JOURNAL OF PHOTOGRAPHY for the library, and thanks were accorded for the same.

After some remarks from Mr. J. R. STONE, J.P., who spoke of his experience and visits to Norwegian scenery, Mr. E. H. JACQUES read a paper on *Holiday Trips with the Camera in Norway* [see page 198].

The paper on the 28th instant will be on *Various Printing Processes*, by Mr. W. Griffiths.

BIRKENHEAD PHOTOGRAPHIC ASSOCIATION.

MARCH 14.—The President (Mr. Paul Lange) in the chair.

Messrs. W. C. Bustard, F. E. Patchet, and E. P. Hale were elected as members.

The PRESIDENT, in compliance with his promise of February 14 re "outdoor excursion competition," then read the conditions of the competition for which he has promised a silver medal, and which reads as follows:—"For the best set of six pictures taken on an excursion to take place on a Saturday afternoon, probably in May, 1889, place of excursion to be posted to each member two days before the date fixed for the trip. All subjects eligible for competition. The chief point of merit for the award to be artistic selection of subject, and next, the number of results obtained by any competitor out of six exposures. It is to be understood that each competitor is limited to six exposures only."

The PRESIDENT read a letter from the Birmingham Photographic Association in which they state that they had sent on a loan of two hundred slides which had been taken by the members of their Association. In return for this kindness the President urged the members to send in some slides on loan to the Secretary, so that we may return the compliment by sending slides done by our members to the Birmingham Photographic Association.

Mr. Kerry exhibited a detective camera which he had made from his own lens, and with which thirty plates could be exposed with very little trouble, there being no necessity to use dark slides for same.

Messrs. H. B. Sharpe and W. B. Beaton exhibited some stands, developers, shutters, &c., which met with much commendation from the members present.

The President exhibited the silver medal which he had received from the Vienna Exhibition, its magnitude surprising many present.

The PRESIDENT then announced that Mr. B. J. Sayce would give a demonstration of the development, &c., of Eastman's paper negatives.

Mr. SAYCE, in proceeding with his demonstration, stated that the full instructions given by the makers with each spool of paper would be found sufficient to produce excellent results. He then cut off with a pair of scissors an exposure from the spool, using a sheet of glass, half-plate size, as a gauge; having soaked the sheet in water, which he poured frequently off and on both sides to avoid air bubbles, he then commenced to develop with the normal pyro, sulphite, and carbonate of soda, without bromide. At this stage a difficulty occurred with the position of the red lantern, and on its correction it was found that the exposed surface had darkened to an extent which caused the bystanders to believe that no negative could be secured on account of over exposure, though the actual exposure had only been cap off and on at ten minutes to nine a.m. on a dark subject with $f/22$ stop of Wray's rapid rectilinear eight-inch focus lens. Mr. Sayce promptly changed the solution to acidulated pyro and sulphite, with bromide, and development being arrested, density began to assert itself; the finishing touch was a double dose of the carbonate of soda solution, and when fixed, to the surprise of all, a vigorous bright printing negative resulted. A second exposure of the same subject, but with $f/16$ stop, was treated from the onset as an over exposure, and two excellent negatives produced scarcely differing from each other and perfectly free from grain. Mr. Sayce holds the opinion that grain is entirely due to uncorrected over exposure, and with proper exposure or proper development it will not show even when lantern transparencies are made. He added that the film being acted upon from two sides answered to the developer or the restrainer much more quickly than the same film on glass where one side is sealed, and thus there is more latitude in exposure. The operation ended by the negatives being squeezed on opposite sides of a sheet of elastic, and in this condition they were extremely portable. Mr. Sayce mentioned that he never oiled his paper negatives, and only stripped the films when many prints were required.

Mr. H. B. SHARPE then proceeded to develop a Carbutt celluloid film, eclipse brand, sensitometer 27, exposure one-fortieth of a second, Aptas rectilinear lens, picnic basket, detective camera, very dull day, threatening rain. The developer he used for same being hydroquinone, Thomas's formula. After development had taken place, the film negative was passed round, the density of which was marvellous. Mr. Sharpe stated that before pinning the film up to dry it should be treated with a bath of glycerine, one ounce, and water, twenty ounces. This he said would prevent the films from curling when dry.

BRISTOL AND WEST OF ENGLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

FEBRUARY 20.—Colonel Playfair in the chair.

The present position of the Association having been discussed, a strong feeling was manifested in favour of increasing its efficiency and influence.

It was proposed by Mr. HOOD DANIEL, "That the Association be continued, and that its future be dependent on the attendances from now until the end of the year."

The motion was seconded by Mr. E. BRIGHTMAN, and carried.

The Chairman then received the resignation of Mr. Brightman of the post of Secretary and Treasurer, which he has most efficiently fulfilled since the resignation of Mr. Hood Daniel.

It was agreed that the names of certain members in arrears for their subscriptions should be posted in the Association's rooms.

Mr. BRIGHTMAN announced the resignation by Mr. Davey of the post of President.

Mr. Daniel was elected to that office, and Mr. F. Bligh Bond to be Secretary and Treasurer.

The Chairman and Mr. Brightman were nominated Vice-Presidents, and Mr. Tribe and Dr. H. Brown, Auditors.

The Committee were then re-elected, Mr. Norgrove's name being substituted for that of Mr. Boyden.

DERBY PHOTOGRAPHIC SOCIETY.

MARCH 12.—Mr. Keene presiding.

One member was elected.

Mr. A. H. BENNETT read a paper on *Cycling as an Aid to Photography*.

On March 14 the Society entertained the members of the Nottingham Photographic Association at their rooms, when about thirty availed themselves of the invitation, including the President, Mr. H. Blandy; Vice-Presidents, Messrs. G. A. Bull and S. Wells; and the Hon. Secretary, Mr. P. E. Knight.

After a hearty welcome by Mr. Keene, an exhibition of lantern slides made by the members of the Derby Society was given, amongst the exhibitors being Messrs. Keene, Scotton, Bounlin, Cooper, Lovejoy (Hon. Secretary) Chadwick, and Dean.

After some remarks by Mr. Blandy, it was arranged that the two Societies should meet at the trip to Ashby-de-la-Zouch on April 27.

The walls were tastefully decorated, and hung with a large number of photographs taken by members of the Society.

The gathering afterwards resolved itself into a smoking concert.

IPSWICH PHOTOGRAPHIC SOCIETY.

MARCH 12.—Mr. J. Dixon Piper in the chair.

Mr. P. Woods (Stowmarket) was elected a member.

Mr. J. C. WIGGIN read a paper on the *Chemistry of Photography*, and illustrated the same with numerous experiments showing the various chemical reactions taking place in the different photographic processes.

In the discussion that followed the PRESIDENT remarked that Mr. Wiggin was one of the earliest workers in platinum printing, and many years ago showed him prints by that method.

A lantern night is fixed for April 9.

LEICESTER AND LEICESTERSHIRE PHOTOGRAPHIC SOCIETY.

MARCH 13, Mr. George Bankart (President) in the chair.

The meeting was devoted to the exhibition and award of prizes for general outdoor work by the members, being the first local competition which has taken place since the formation of the Society. Each member competing contributed six mounted prints in one or both of two classes, viz., Class A, for prints upwards of half-plate size; and Class B, for prints of half-plate and under; and though the entries were not so numerous as might have been desired, the average quality of the work was good. Silver and bronze medals had been presented to the Society—in Class A by Mr. W. S. Hobson (past President), and in Class B by Mr. Bankart (President), the medals having been founded specially for the use of the Society.

After an afternoon and evening devoted to the careful examination of the prints, the award of prizes was made by ballot, each member present being entitled to two votes in each class, one for the silver and one for the bronze medals, the voting being for the *best average of six prints*, and not for individual pictures, and the result justified the expectation of the proposers of this method of deciding the winners, and corresponded almost exactly with a forecast made by two members of the Society qualified to form an opinion on the subject, except that in consequence of the nearly equal merit of work two winners changed places in the voting.

The voting for the silver medals took place first, by general desire, in order to avoid confusion as to record of votes for the bronze medals, the result proving strongly in favour of Mr. Bankart for Class A, and Mr. J. Porritt for Class B. The voting for the bronze medals was much closer, and illustrated considerable variety of opinion, the result being finally in favour of Mr. W. T. Tucker, of Loughborough, for Class A, and Mr. A. W. Wilson for Class B, though Mr. S. S. Partridge was only one vote behind Mr. Wilson.

The system, though novel, seemed to work smoothly and to give general satisfaction, and as the names of competitors were not stated and the prints classed by numbers only, there can be little doubt that the awards were correctly made on the actual merits of the work.

NOTTINGHAMSHIRE AMATEUR PHOTOGRAPHIC ASSOCIATION.

On March 14 a party of the members made a return visit to the Derby Photographic Society, and were met on the Derby platform by a deputation who conducted them to the Society's new rooms, where they were heartily received by the members of the Derby Society. A large collection of photographs was displayed upon the walls and tables, especially noticeable being the prints taken during the Photographic Convention held in Derby in 1887. The visitors were then "shown about Derby" (on the screen), some very fine views being exhibited. Refreshments having been partaken of, the President of the Nottinghamshire Association proposed a vote of thanks. The return journey was made by the quarter-past ten p.m. train.

On Monday evening, March 18, the usual fortnightly meeting of the Association was held, when a number of the novelties of Mr. Tylar, Birmingham, were exhibited. The President (Mr. Henry Blandy, L.D.S.) occupied the chair.

Mr. John Merriman was elected a member.

Mr. J. C. LANCASTER read a paper on *The Magic of Science; or, a Night's Amusement with Photographic Chemistry*. Mr. Lancaster said:—

The title of my paper is, perhaps, a somewhat unusual one, and I may say at the very outset that I do not propose to enter into the art of mystery, or even to closely define the meaning of the word magic. It may mean imposture or acting, by practising the secret operations of natural powers, or, in other words, apparent deception.

Again, science is defined to be knowledge grounded on demonstration or art built on mere principles, and, by inversion of terms, we arrive at a scientific deception. Deception by means of scientific experiments now serves only two useful purposes—one is instruction and the other is amusement. In early times, however, it was otherwise, for science combined with deception served only one purpose, for does not universal history tell us how powerful an instrument it was when employed to awe the people by their rulers?—and to this end prince, priest, and sage were leagued together to impose upon the masses, who at times could not be impressed unless by what they in their ignorance considered to be supernatural. The means they employed would seldom deceive people living at the present day, who are daily accustomed to some optical or acoustical wonder due more or less to scientific contrivance; although in a harmless way, one may still practise devices which threw the judgment entirely at fault, no matter how educated one may be, and I think it will not be difficult to show by the very simplest means how the senses of vision, hearing, and touch may be readily deceived. [Experiments on this were then given.] When our judgment has played us false, as in the instances just given, we have been, without doubt, victims to a kind of deception which has been termed scientific for the simple reason that it comes within the pale of science to analyse and ascertain all that it is possible to learn concerning these peculiar and singular phenomena, magic photography. A few years ago small pieces of white paper were offered for sale which on being covered with blotting paper and sprinkled with water displayed an image as if by magic. The sheets of white paper, to all appearance a blank, were in reality photographs which had been bleached by immersion in a solution of chloride of mercury; in the blotting paper sold there was hyposulphite of sodium; this was dissolved on moistening the paper, the solution penetrated to the picture and made it visible. The magic elgar holders were then fully explained, as were indelible inks. Experiments were given, as alcohol dropped on chromic acid immediately taking fire; fire produced by dropping H₂SO₄ on chlorate of potash and lump sugar; turning iron into gold, silver, or copper, &c.

The proceedings then terminated.

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES' PHOTOGRAPHIC ASSOCIATION.

MARCH 12.—The President (Mr. A. S. Stevenson) in the chair.

The PRESIDENT, in thanking the members for having honoured him in electing him to the position he held, spoke of the great advancement which had taken place of late years in the photographic art. He himself lectured on the subject in the Hall of the Literary and Philosophical Society about thirty years ago, and at that time hardly anything was known of photography by the public.

It was announced that Mr. Stevenson would give a silver and bronze medal for the best and second-best series of not less than twenty-four lantern slides, open to all professional and amateur photographers in the world; and also that Mr. J. P. Gibson would give a silver and bronze medal for the best and second-best series of six lantern slides by an amateur member of the Association. The competition for these will take place in November, 1889.

Mr. H. C. HEMY read a paper upon *Lenses—Photographic and Microscopic* [this will appear in a future number], and numerous examples were shown.

At the next meeting, April 9, Mr. J. P. Gibson will read a paper on *The Intensification and Reduction of Negatives*.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

MARCH 7.—Mr. William Lang, jun., F.C.S., in the chair.

The following gentlemen were admitted members of the Association:—Messrs. E. B. Clark, W. Anderson, J. W. White, J. Humphreys, A. Fitz-Conroy, W. Smith, B. Simons, J. E. Hanbridge, J. Dove, D. Dove, Councillor J. M. Primrose, and Dr. J. C. Woodburn.

Mr. ADOLF SCHULZE read his paper on *Photo-micrography*. Beginning with a description of the microscope and the various lenses in use, he went over the points of his photo-micrographic apparatus. This was compactly arranged on a long table. At one end the microscope itself rested on a turntable, so that when the object to be photographed had been properly set on the stage plate a simple movement of the turntable brought the microscope and Dallinger paraffin lamp into position in front of the camera. The focussing screen was a sheet of clear glass on which the enlarged image could be readily seen with a focussing glass. A long rod brought the fine focussing adjustment of the microscope within reach of the operator at the back of the camera. When photographing objects which could not be placed in a vertical position the whole top of the table could be turned on end and the focussing worked from the top of a step ladder. Mr. Schulze gave a demonstration and produced a very good half-plate negative of the proboscis of a fly.

A large number of photo-micrographs were then thrown on the screen and explained by Mr. Schulze. The one which provoked the greatest enthusiasm was a group of one hundred and sixty diatoms.

Correspondence.

Correspondents should never write on both sides of the paper.

CAMERA CLUB CONFERENCE.

To the Editor.

SIR,—Would you kindly give a notification in this week's BRITISH JOURNAL OF PHOTOGRAPHY that the Camera Club Conference will be on at the Society of Arts on Tuesday and Wednesday, the 26th and 27th of March, and that all interested in the subjects are cordially invited to attend the meetings, including the International Lantern Exhibition at 8 p.m. on Tuesday, the 26th, at the Society of Arts?

Slides have been sent to us from French, Austrian, and American Societies for this Exhibition. All the meetings are open to ladies.—We are, yours, &c.,

G. DAVISON,
E. G. SPIERS, } Hon. Secs.

Camera Club, 21, Bedford-street, W.C., March 18, 1889.

PERMANENT HYDROQUINONE.

To the Editor.

SIR,—We are reluctant to trouble you again in this matter, but our rivals in your last issue charged us with treating them unjustly. The charge should, we think, emanate from us, and if there be reason for complaint it is on our side, inasmuch as they just made a statement with regard to permanent hydroquinone which yourselves, Mr. Levy, and Dr. Byk have emphatically proved to be incorrect. They do not now attempt to substantiate their original complaint, but merely try to lead the public off with the cry of unjust treatment to which we reply, "*qui s'accuse s'accuse*."

Your correspondents write as if they alone supplied "pure" chemicals, and as if photographers required to be told the custom of the chemical trade, and that purity is at best but a relative term. It is just seven years since they wrote (March 31, 1882) an interesting and instructive article on *Chemical Purity*, from which we make the following extract:—

"The most careful and skilful operator cannot prevent a variety of adverse results attending the use of indifferent chemicals. Following up the interesting controversies which form the principal subject of the JOURNAL, it cannot fail to escape notice that they turn more or less upon the varying purity of the reagents employed. As Mr. Schering has very properly observed, it is necessary to speak of 'photographic purity' as a something superior to ordinary chemical purity, in the same manner as we are in the habit of speaking of analytical purity as a something characterising a higher degree of the ordinary term of 'chemical purity.'"

It was to obviate this *varying purity* that Dr. Byk sought, and, we believe, has successfully achieved in introducing his *permanent hydroquinone* which Messrs. Schering's agents are pleased to term a "compound," but which has been proved to be at least equal in quality to the "pure and real" article which they are so zealous in distributing.

Truly our friends may say, "*tempora mutantur et nos mutamur in illis*." In the course of a few days we hope to send you Dr. Byk's own remarks on the whole question.—We remain, yours, &c.,

27 & 28, Jewry-street, March 19, 1889. BERNSTEIN & VOOT.

THE CONSTITUENTS OF AZALINE.

To the Editor.

SIR,—Allow me to make a correction respecting the exact name of the chemist whose analysis of Dr. Vogel's azaline you were kind enough to publish last week. His correct name is not Dr. O. W. de Witt, but Dr. Otto N. Witt, the same gentleman mentioned by Mr. J. Spiller as his friend in a previous letter, and, therefore, a well-known authority on such matters.—I am, yours, &c.,

19, Buckingham-street, Strand, March 18, 1889. J. R. GORTZ.

PSYCHIC PHOTOGRAPHY.

To the Editor.

SIR,—In reference to your suggestion as to the ultra-violet rays alone being the source of chemical action in the psychic photographs, it occurs to me that some elucidation might be given to the matter by the employment of a sheet of paper coated with sulphate of quinine in place of the gelatine plate.—I am, yours, &c.,

Clifton, March 18, 1889. Geo. S. THOMSON, M.D.

P.S.—Some years ago I made some experiments in the matter, but they were unavoidably interrupted.

A REMEDY FOR THE BICHROMATE DISEASE.

To the Editor.

SIR,—The use of bichromate of potash has become so general in photography, and its effects on the health are so serious, that I think it is my duty to indicate to my fellow carbon printers a remedy which I have found most effective. Naturally the greatest care is necessary in handling this salt, whether in its dry state or in solution. In sensitising one should always use indiarubber gloves, and, above all, it is necessary to live soberly and refrain from all excess which might endanger the purity and vigour of the blood. During development the hands should be brought as little as possible in contact with the bichromate, as the warm water opens the pores of the skin and renders it liable to absorb a large quantity of the salt, but gloves are much in the way of a professional printer when there is a quantity of work to be got through. The amateur should always use gloves. The presence of the salt in the tissues causes violent irritation and an irresistible inclination to rub the parts most affected. In winter especially, when the skin is chapped, the action of

the bichromate salts is really terrible, and the results may be most dangerous.

Fifteen years' practical experience at the establishment of M. Stroud, in Jersey, where carbon printing is a speciality, has rendered me conversant with all the difficulties and dangers incident to the carbon printer. I have taken the precautions indicated, and, even in winter, though my fingers have been covered with cracks, they have never been more than very slightly attacked, and I have never been obliged to discontinue my work even for a day. Below is the remedy which I use; it is very simple, and after one or two applications (with friction) all cutaneous disorders disappeared. It is as well to use it every day, after work is over, as a disinfectant.

Glycerine ½ ounce.
Pure carbolic acid 10 drops.
Water 2½ ounces.

—I am, yours, &c., BEAUMONIS, Carbon Printer.
Stroud Establishment, Jersey, March 19, 1889.

PHOTOGRAPHING IN ITALY.

To the Editor.

SIR,—In reply to "X. Y. Z." about photographing in Italy, I think he need not be afraid of any interference from the police or the Customs. I have passed the frontiers a good many times, mostly with a lot of glass plates, and on only two occasions was I very near having my plate boxes examined. Each of those times I was allowed to pass after explaining the nature of the plates contained in the boxes. Still, one cannot help feeling anxious at the possibility of having to show some of the sensitive films.

As I am starting early in April for a long Italian tour, if "X. Y. Z." likes to communicate with me we might arrange a meeting.—I am, yours, &c.,

P. H. FINCHAM.
West Dulwich, S.E., March 19, 1889.

To the Editor.

SIR,—In reply to "X. Y. Z." I can only speak for Northern Italy, having three years ago entered from Germany via the Brenner Pass, and, after visiting the chief towns, gone out again by the St. Gothard.

I had no trouble at all with the Italian Customs authorities, although I carried a good stock both of films and glass plates. On the other hand, I had endless contests with both French and German Customs, the latter forcing me to pay duty twice, although the stamps from the first payment were still attached to my boxes. My advice to the photographic amateur is, therefore, avoid France and Germany.

Three years ago only the ordinary Eastman paper (spools) was in the market, and that I used. The rapid would be best for groups, market scenes, or shots from the train. The Gothard carriages are the long Swiss make, open at the ends, and I set up my camera in the doorway of the last carriage, and worked away as the train rattled along. A quick lens and shutter are necessary for this.

Although this trip was taken in August, I did not find the light any stronger, actinically, than further north. But I place no trust in exposure tables; inactin and experience are better than any tables I ever used. When in doubt develop a plate or two, and so acquire certainty. Chemicals (saturated solutions) take up very little space, and any hotel chamber at night gives a sufficient dark room. I never carry a lantern. One or two thicknesses of canary or ruby cloth round the tripod legs have done efficient duty for years, whilst a few extra lengths and some drawing pins soon dispose of leaky doors or windows. I had no trouble in North Italy from police or crowds, even in the towns or at stations.—I am, yours, &c.,

KENNIS B. MURRAY.

Botolph House, Eastcheap, London, E.C., March 16, 1889.

DETECTIVE CAMERAS.

To the Editor.

SIR,—In the last number of the JOURNAL a description is given of a detective camera by Mr. Gaskin Wood. The camera is well known to those who have had any lengthened connexion with photography. It is simply a copy of a camera which was invented by Mr. Aird about seventeen years ago. In the early part of 1875 Mr. Aird read a paper before the Edinburgh Photographic Society, describing the camera and showing drawings of details. These were duly published in full in your JOURNAL at the time. Messrs. Kemp & Co., of Edinburgh, made several.

Mr. Aird exhibited his camera at the large photographic exhibition held in Edinburgh, December, 1876, and was awarded a medal for it. In the meantime, from the drawings and description published in 1875, M. Ionté, of Paris, constructed an improved "Aird's Camera," several of which I have seen, and had an automatic arrangement which punctured a strip of paper, showing what plates had been exposed. An article on this camera will be found in the JOURNAL of March 24, 1876.

Both these cameras after a time went out of use, the principal reason being the very large bulk and weight the camera assumed when made of any size, and the Siamese-twin character it had of having to carry the whole affair into the dark room when filling, emptying, or developing the plates. It altogether proved too cumbersome, and instead of replacing double slides, as was expected, it was eventually found that slides were much better, and the camera was relegated to the limbo of the past.—I am, yours, &c.,

PYLOS.

Edinburgh, March 19, 1889.

[On looking up the description of Aird's camera we find the one described last week to differ in several essential features.—ED.]

COPYRIGHT IN AMERICA.

To the Editor.

SIR,—I wish to copyright some pictures in the United States, kindly give me particulars and tell me how to proceed.—I am, yours, &c.,

S. J. WELLS.

[The term of copyright in the United States runs for twenty-eight years, but within six months before the end of that time the author, or designer, or his widow, or children, may secure a renewal for a further term of fourteen years, making forty-two years in all; but you cannot obtain what you desire, for citizens or residents of the United States only are entitled to copyright. ED.]

A COUNTY PHOTOGRAPHIC GUIDE.

To the Editor.

SIR,—Was there not a suggestion made, some time ago, that each Photographic Society throughout the kingdom should supply or publish hints and particulars as to the best "bits," historical subjects, &c., in its immediate vicinity?

I should now like to ask if it would not be worth some publisher's while to compile "a series" of local guides on some systematic plan? You, sir, have done so well with your ALMANAC, and, being in communication with all the Societies, could, it seems to me, best undertake such a venture. The cyclists find that it pays to publish literature of this sort; the photographic amateurs now form an army so large that they would, I should think, supply a good market for such guides.

If urged thereto, say, by the Parent Society, or the Camera Club, the country Societies would, I have little doubt, nominate Committees to obtain information from their members, which could be supplied to a centre in London and published cheaply. Could we commence with a "sub-urban London?"—I am, yours, &c.,

PROGRESS.

March 15, 1889.

Exchange Column.

* * No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

Will exchange 15×12 Dallmeyer's Triplet for 12×10 camera with three double slides.—Address, H. H., 31, Lynton-road, Crouch End, N.

Exchange, balcony and trelliswork for balcony; must be in good condition.—Address, E. WHITE, Photographer, Radcliffe, Manchester.

Will exchange tall-cased quarter-chime clock for modern tourist's camera and lenses for large-sized plates.—Address, WALKERMAN, Photographer, Shanklin.

Wanted, half or whole-plate portable camera and double slides, lens, and folding stand, in exchange for good limelight dissolving apparatus.—Address, MR. PAINGOLF, 20, Bath-street, Hanley, Staffordshire.

Wanted to exchange, a japanned zinc water-wheel print washer, size of cradle, 16×13, for two good second-hand backgrounds, balcony, or posing chair.—Address, W. TAYLOR, Tregeana-place, St. Ives, Cornwall.

Dallmeyer's stereographic portrait lens; wanted, whole-plate wide-angle rectilinear. Also would exchange valuable tricycle for 15×12 (or larger) rapid rectilinear or rapid symmetrical.—Address, WATKIN, Oakland-road, Hanwell, W.

RICHARD BROWN.—We are sorry to learn of the death of Mr. Richard Brown, of Liverpool (Brown, Barnes, & Bell), which took place on the 14th instant.

We have received from the Frederick Crane Chemical Company, of Birmingham, samples of varnishes prepared for makers and users of photographic apparatus. Enameloid is a hard, dead-black varnish; which adheres to either metal or wood; protectaline, is a negative varnish possessing a good body; enamelene is a shellac wood varnish for which special properties are claimed. All these articles seem to be valuable to photographers.

Answers to Correspondents.

• Communications relating to Advertisements and general business affairs must be addressed to "H. GREENWOOD & Co.," 2, York-street, Covent Garden, London, W.C.

All matters for the text portion of this JOURNAL, including queries for "Answers" and "Exchanges," must be addressed to "THE EDITOR," 2, York-street, Covent Garden, London, W.C. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.

DENT. Try Judson's.

R. BROOK.—The address is Florence-villa, Cavendish-road, Aylestone-road, Leicester.

J. H. PETERS.—By all means secure a landscape lens for the special purpose mentioned.

PRESTON.—1. By sulphide of potassium.—2. Not worth saving.—3. Same as number one.

W. N.—There is no difference, except as regards mechanical convenience, between the fused and stick form.

1, 2, 3.—Hydroquinone can be employed for the development of bromide enlargements. Some prefer it to the ferrous oxalate.

GEORGE McDONALD.—1. One or four.—2. We employ three, five, six, and eight, and cannot indicate a preference for either.

BOHR.—This is purely a case for a solicitor, who will determine whether there have been misrepresentations or not. We cannot advise respecting the matter.

BLOW-THROUGH. 1. You must employ three lanterns to get the effects you speak of.—2. No, it cannot be done.—3. Not with the lens you at present possess.

A. S. BUTLER.—The writer of the article does not silver glass as a profession. There are several firms in London who do so, and would be very glad to undertake such work as you require.

ATKINSON.—1. Sulphide of potassium.—2. The easiest method is to dissolve the bromide in hyposulphite of soda and precipitate as before.—3. The one with the largest aperture is the quickest.

A. B.—Your picture is spoiled by having such a large uninteresting piece of foreground; had a stray dog or other animal appeared upon the scene at the time of exposure it would have had quite a different aspect.

MISS H.—You can use your lens (quarter-plate) for enlarging heads, but if you wish to enlarge groups, it will be requisite to use a stop in order to get marginal definition, or you can use a lens of longer focus.

WARDER.—If you are using a rapid symmetrical lens for taking refractory sitters, you are certainly working at a disadvantage. You should obtain a quick-acting portrait lens, which will work in a quarter of the time.

D. MACLEAR.—Your experience is not exceptional. It is not every formula that is issued with the plates that is the most suitable for them. If you find your own developer so much better, why trouble further about the other?

N. L. COX writes: "Many of the labels have come off the bottles in my dark room owing to the damp; how can I prevent this?"—Paste the label on the bottle, when dry brush a little varnish over it, this will prevent the moisture acting upon it.

SEPTIMA.—French chalk, or powdered talc, may be had from most dealers in lithographic material; the price is only about sixpence per pound. There must surely be some mistake when you were charged at the rate of five-and-sixpence per pound.

PARAFFIN asks the cause of a paraffin lamp in a lantern smelling, and what will cure it.—Wash the lamp thoroughly, warm it, and fill with oil just before use. The smell is caused by the surface of the lamp becoming coated with oil, which as the lantern heats is given off.

BUENOS AIRES writes: "Can you, or any reader of the JOURNAL, give me any information concerning the Argentine Republic, its climate, and the possibilities of obtaining employment as artist, retoucher, &c.? Any information whatever on the subject would be thankfully received."

S. S.—If the varnish remains tacky for two days after it is applied to the negative, and the paper sticks to it when printing in the sun, it is clear that it should not be employed. Return it to the maker. We cannot say if you can recover the value of the negatives spoilt. We do not express an opinion on purely legal matters.

SUKARINA says: "Some time ago I coated the cells of a lens with black varnish, but it has chipped off. Is there anything besides varnish that will effect this purpose, and if so, what is it, and how is it used?"—Make them quite clean, then apply a solution of nitrate of silver and nitrate of copper, heat the cell, and a fine stain will be the result.

R. WORREY asks if there is any difference between the "powder process" and the "dusting-on process," or whether they are the same process under different names? Also where he can get working details of it or them?—The powder and dusting-on are one and the same process. The working details of it will be found on page 466 of our volume for 1885.

LEVEL.—1. Thanks; the subject is one of great interest.—2. In about two weeks.—3. You need not necessarily have two levels in the camera, one will suffice if it is the proper shape. We employ a circular one about one and a half inches in diameter, which is simply placed upon the camera; when the air bubble is in the centre the camera will be perfectly level.

EYLES R. says: "I noticed a microscope lately with two eye tubes, but one seems to enter into the other at an angle. How is it possible for the eye looking into the oblique one to see the object?"—By means of a prism inserted in the tube at or near this junction, which causes the rays of light to be deflected to the requisite angle. Hence both eyes see the same object.

G. B. W. writes: "By this post I send you some negatives which I developed with ferrous oxalate, but they have several spots upon them."—In reply: The negatives came in a smashed state, but sufficient remained for inspection. The spots are caused by the formation of air bubbles at the time of development. Rinse the plates with water before developing, and if any air bubbles form disperse them with a tuft of cotton wool.

J. J. says: "I recently had sent to me in India some albumenised paper, and on its arrival the sheets were all, more or less, stuck together by damp absorbed in transit. Is it usual to send paper out here simply packed in brown paper between boards? Can anything be done to make the paper workable?"—Usually in sending such goods to India they are secured in metal-lined cases, soldered down; then they travel without injury. There is no remedy for the damage done; the paper is worthless, except perhaps for parcelling.

LUX writes: "Will you direct me as to the best means of connecting a really good Beck microscope, with two-inch, one-inch, and quarter-inch powers, to a camera to photograph minute objects to be ultimately shown by the optical lantern? I am entirely ignorant of the method of connecting the two, although accustomed to do tolerably good work with either single."—Tilt the microscope in a horizontal position and connect it with the camera. If the camera will not extend sufficiently to make an image the size desired, an extension cone may be used to connect them.

A. C. W. writes as follows: "I am making myself a detective camera to take instantaneous lantern negatives on quarter-size plates, and ask your opinion as to the most rapid lens I can use for the purpose. Last year I used a lens working at f-8, but that is not nearly quick enough for my present purpose. How would a portrait lens do?"—The quickest lens, and one that will be most suitable, is what is known as an "instantaneous stereoscopic lens," which works at an aperture of about f-3, and will cover a lantern-size plate very well. It is a modified Petzval combination.

J. R. WHITE complains that in mounting prints on glass, as "opalines," he cannot get the prints flat owing to the gelatine setting before the excess can all be squeezed out. The gelatine he says he employs is ordinary dry plate gelatine. The trouble, no doubt, arises from the sample of gelatine being unsuitable, or maybe the solution is too thick. The gelatines usually employed for dry plates are quick-setting ones, and are, consequently, not well adapted for mounting purposes. Our correspondent should obtain another kind with tardy setting properties, such as Nelson's No. 2 soluble.

A SEVEN YEARS' SUBSCRIBER asks how he can obtain a finer ground glass than that generally used for the focussing screens of cameras?—The fineness of the grain is dependent upon the fineness of the emery with which it is ground. To obtain the finest emery, take some "flour emery" and stir it up in a large jar of water; allow it to stand for a few minutes for the coarser particles to subside, then decant the water into another jar. The fine emery suspended in the water will in time settle to the bottom of the vessel, and may then be collected. Now take a piece of patent plate glass and grind it with this fine emery, using a piece of thick plate glass as a muller.

C. WAINE says: "I have been making some experiments in photo-lithography, but with no success. I have not got a lithographic press, so have been using my rolling press, which is a very powerful one. Do you think my failure is due to the want of a proper press or to other causes?"—With regard to the probable cause of our correspondent's failures it is impossible for us to say. In a lithographic press the pressure is a scraping one, and not a rolling one. In experimenting in a new (to him) process, makeshift appliances should always be avoided if possible. Our correspondent may possibly be able to obtain the use of a press at a lithographer's in his neighbourhood, and perhaps the aid of the printer.

A. FRASER.—1. For enlarging by the electric light you require a "focus-keeping lamp." The Siemens arc lamp that you name is one of the best you can have; the price, if we remember rightly, is about sixteen pounds. It is not necessary that you have a dynamo on the premises to feed it, if you can obtain the current from an installation in the neighbourhood. But, mind, it must be a continuous, and not an alternating current.—2. So far as we are aware the process is not commercially worked in England nor is it patented. No fuller working details are given than appear in the article referred to. The details, as in most photo-mechanical processes, you will have to work out to suit your requirements by experiment.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—Technical meeting, Tuesday March 26, at the Gallery, 5A, Pall Mall East.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, March 27, will be *Lantern Matters*. This is a lantern night, the last of the season.

No. 1508. Vol. XXXVI.—MARCH 29, 1889.

DEPTH OF FOCUS IN PORTRAITURE.

FOLLOWING the reading of a paper *On Depth of Focus* by Mr. Conrad Beck at the Camera Club Conference on Tuesday, arose, in the discussion thereon, the subject of the desirability of lenses for large heads, the construction of which, with a fairly large angular aperture, there should remain a certain amount of uncorrected spherical aberration. This, by removing the acme of definition, optically speaking, from the nose of the sitter, should prevent, by contrast, other planes of the face—the eyes and ears for example—from seeming to be out of focus. Let it be at once understood that our remarks at present are confined to the direct production of large heads, and to this alone, landscapes or copying not here entering into the computation.

Is absolute optical sharpness desirable in a large head? Not by any means. As we stated, microscopic sharpness in one plane—that of the nose for example—while quite undesirable in itself, would be a sorry counterpoise for a serious falling away in the definition of the eye or ear, to which it would act as a foil in virtue of its very sharpness. Far better a pencil-point sharpness throughout than a steel-pen sharpness in one place and a crayon sharpness in another. This kind of definition cannot be obtained by a portrait lens corrected in the highest style by a good optician. We well recollect, when this subject was brought before the the Nottingham meeting of the British Association in 1866, by the late M. A. Claudet, in a paper *On a New Process for Equalizing the Definition of all the Planes of a Solid Figure represented in a Photographic Picture*, this eminent *savant* and clever photographer spoke of excessive minuteness being the greatest reproach made by artists to the best photographic portraiture, in order to obviate which some had suggested taking the portraits a little out of focus. Having combated this from a scientific point of view, M. Claudet showed by what means a compromise might be made, in virtue of which the lens was made to travel backwards and forwards to ensure each plane of the face and figure being brought into sharp focus at one stage of the complete exposure, thus removing, if possible, from photographic portraiture that "mechanical harshness" due to the action of the most perfect lenses. The present writer then suggested that the object aimed after, viz., the diffusion of the focus over several planes, could be better obtained by optical means more specially adapted for the purpose, and he then and there exhibited a portrait of large dimensions made by Mr. H. P. Robinson by a modified triple lens, in which the central element was very much larger than any previously constructed, and which, when worked with full aperture, gave precisely the same class of soft definition as that secured by the more cumbersome system of M. Claudet.

What we desire at present to point out is this, that assuming

crisp definition not to be the desideratum for the special purpose in hand, a single lens, worked at a larger aperture than that at which any high-class optician would care to send it out, will give the effect desired, which we once more repeat is soft in contradistinction to sharp optical definition. The easiest way for a photographer to get this with the means at his disposal, is to take a portrait lens of any make, remove the back combination entirely, and transfer the front one to its place. In this state it will give an image of a more or less confused nature, but by commencing with the largest diaphragm and proceeding downwards, carefully examining the definition at each step, one will be eventually found by which a delicious softness of definition will pervade the image on the ground glass. This, it will be observed, is only a species of landscape lens worked with a larger aperture than usual; but what signifies the nature of the tool, or the name by which it is known, so long as it serves the purpose desired?

BICHROMATE OF POTASH AND ITS PHYSIOLOGICAL EFFECTS.—II.

IN this article we shall indicate more fully the first symptoms of the pernicious effects of the bichromate as used in photography, and the best remedies to apply. As already stated, the injurious action of the salt may be experienced in two different forms. One is from the use of cold and comparatively strong solutions, which result in unpleasant, and sometimes serious, wounds. The other from the more continuous employment of warm and dilute solutions, such as are formed in the development of the bichromated gelatine image in warm water.

The first form of evil is not likely to occur unless there happens to be an abrasion of the skin at the time the solution is employed. We have it, on the authority of those medical men who have given most attention to the subject, that the hands and arms may be continually immersed in concentrated solutions without injury, provided the skin be intact. If, however, it be broken an inconvenience, though not necessarily a lasting one, will be experienced.

Supposing, for example, in using a solution of the salt, there happens to be a hitherto unknown scratch in the skin, it will be immediately rendered manifest by a smarting sensation. Now the part should, without loss of time, be well washed for a minute or two under the tap—the water being allowed to impinge on the place. Then it should be sucked for a few minutes to get out the poison. After this simple treatment no further inconvenience will, as a rule, accrue. If, however, after the lapse of a few hours any smarting is again felt, the part should

be soaked in warm water for a time, and afterwards bathed with very dilute ammonia, followed by poulticing. It is seldom, when this treatment is adopted, that any ill-effects result; but if it is not, a painful wound may follow. An ulcer often forms which continues to eat deeply into the flesh, frequently till it reaches to the bone, and obstinately defying all efforts to heal it; and when the wound does ultimately heal a deep scar remains. We have seen several such scars on the hands of those who have suffered.

This particular action of the bichromate is not confined to human beings alone, as it affects the lower animals as well. Mons. Chevalier and Bicourt, in the *Annales d'Hygiène Publique* in 1863, mentioned the case of a horse, employed in a factory in carrying the salt, which was attacked in one of its legs. The suppuration, they say, went on over nearly half its body, and finally resulted in its death. It is also mentioned by these gentlemen that dogs and cats at the factories, through walking on the refuse, were frequently affected in the feet; and that on one occasion a rat was killed which was found to have all its feet suppurating and partially destroyed.

The second form of evil, that arising from the use of the bichromate in warm dilute solutions when the skin may be intact, takes the form of a disease. It is purely a cutaneous one, and is confined to the hands and forearms, or such parts as come in contact with the solutions. The premonitory symptoms in this instance are an irritation on the backs and sides of the fingers, which if closely examined will show minute watery pustules. At this early stage the disease somewhat resembles one form of *scabies*. Indeed, we have been informed, it was once mistaken for it by some medical students at one of the London hospitals.

When the symptoms above indicated make their appearance, it is unmistakable evidence that precaution should be immediately taken, and remedial measures adopted if further inconvenience is to be avoided. The hands should be frequently washed, using "coal tar soap"—carbolic compounds, it may be mentioned, appear to be generally beneficial at the early stages of the disease. At bedtime strong nitrate of mercury ointment—the *Unguentum Hydrargyri Nitratis* of the *Pharmacopœia*—should be applied, sparingly, but well rubbed into the affected parts. If this treatment be followed for a few days, and the use of the bichromate discontinued, or only employed when the hands are protected with indiarubber gloves, further trouble is seldom experienced. If, however, the use of the salt be continued, and no remedial steps are taken, the disease in time, though sometimes slowly, assumes very unpleasant proportions, such as those described a fortnight back.

In the advanced stages of the disease, when the skin dries up and exfoliates the itching becomes almost intolerable. Then the best palliation is the lotion given by Mr. E. W. Foxlee in our ALMANAC for 1885. It stands thus:—Alcohol, five ounces; crystallised carbolic acid, forty grains; glycerine, four drachms. If this lotion causes a painful smarting, which it may do if the skin is much cracked, a little water may be added, or a dilute solution of the subacetate of lead may be used. But the former lotion is the best if the smarting it produces can be borne. The treatment here described appears to be the best at present known.

Prevention is at all times better than cure. Whenever there is known to be an abrasion or other injury in the skin, that part should be protected from the action of the salt. Also after work, in such operations as developing the gelatinous image with hot water, thoroughly wash the hands in warm water, using

by preference a carbolic soap, and afterwards well rinse them in cold water. In no case should the hands be wiped after using a solution—however dilute it may be, even with the developing water—without first washing and rinsing them under the tap to ensure the removal of every trace of the salt. Furthermore, as soon as the first symptoms of the disease show themselves, all future work should be done in rubber, or other impervious gloves.

The bichromate seems to be very erratic in its action. Many persons have used it even in a very careless manner for a great number of years without ill-effect. Others, on the contrary, have suffered badly after working with it only a few weeks. As we mentioned in the previous article, there appears to be but little risk of ill-effects from the bichromates as they are used in photography, provided proper care, such as above described, be taken, even when working on an extensive scale.

EXPOSING TRANSPARENCIES.

In our previous article we called attention to the necessity for tolerable accuracy in timing the exposures of transparencies, and briefly pointed out the comparative ease with which gaslight exposures may be made with a fair amount of certainty. It is, however, in employing daylight or the more powerful forms of artificial light, such as magnesium, and especially with gelatine plates, that the real difficulties of transparency making will be experienced.

For contact printing on gelatine plates, we should always endeavour to dissuade beginners from even attempting to employ these stronger sources of light, for though in skilled hands it may be possible to get good results, it is almost hopeless in the case of the inexperienced. Not only is it next door to an impossibility to give a sufficiently short exposure to negatives of moderate density—that is to say, to perform the mechanical operation with sufficient rapidity without some elaborate arrangement for the purposes—but it is also to be taken into account that the deposit of silver forming the highest lights of an average negative at the present day is not sufficiently thick to protect the exquisitely sensitive surface from the action of light, however brief the exposure may be. In other words, powerful daylight or magnesium light will penetrate every portion of a negative of ordinary density, and consequently it will be impossible to secure transparent lights or sufficient contrasts in the positive.

We do not mean to say that negatives cannot be made that would be suitable for daylight printing upon rapid gelatine plates, for occasionally such a one will be met with, one which, in fact, requires daylight or similar powerful means, and is incapable of giving a satisfactory result with any other kind of illumination. What we mean is, that unless negatives of special density are made for that purpose alone, the powerful light is not practically available, and to make such special negatives would be to render them unfit for any other style of printing. As gas or paraffin are everywhere available, and in every way superior for contact printing, there is therefore no reason for going out of the way to raise trouble.

With gelatino-chloride or collodion emulsion plates, on the other hand, the more powerful forms of light may be utilised with advantage, even when the exposures are made in the ordinary printing frame, though still with these slower films the exposure must be brief and carefully adjusted. For camera printing on such films, daylight alone can be said to be avail

able to the amateur, as the exposures necessary with gas or similar light are so prolonged, while electric light or limelight are not often likely to be available. With magnesium at its present price that medium may perhaps be pressed into service, but a properly constructed lamp will be needful; and even then it is difficult to see what advantage is gained over daylight, which costs nothing, unless the operator be unable to avail himself of daylight hours.

Turning back again to gelatino-bromide plates exposed in the camera, we have the choice of every kind of light, from daylight to gaslight, the range of sensitiveness of the films bringing them within the scope of all, without necessitating either inconveniently short or inordinately long periods of exposure.

We think, undoubtedly, that the best light for general purposes is daylight, using, of course, diffused light preferably falling direct from a clear sky upon the negative. When we say "clear" sky we do not speak in the sense of "cloudless," but merely of a sky unobstructed on the one hand by terrestrial objects, or having the uniformity of its illumination destroyed by heavy or irregular masses of cloud or broken sunshine on the other. What is wanted is a tolerably even sky, no matter how apparently "dull" if the general quality of the light be good; indeed, a clouded sky is superior to one of unbroken blue, and if the clouds be of the white, fleecy character, the light will be the very best that can be obtained both for uniformity and rapidity.

It not unfrequently happens, however, that a direct and clear view of the sky cannot be secured, or, at least, that it is not conveniently available for printing purposes. Under such circumstances it will be necessary to use reflected light in the manner so frequently described. The reflector may consist of silvered glass, opal, or other dull white surface, as may be most convenient, but the first named is the best for general purposes. For merely printing transparencies it is scarcely needful to resort to any elaborate permanent arrangement of reflector as is usual for enlarging purposes. It will generally suffice to fix the reflector at the proper angle, 45° , on the end of a board which is caused to project outside the window, the negative being arranged in a vertical position on a table within the room, and opposite to the source of borrowed light so produced; the brilliancy of the image produced upon the ground glass will of course depend upon the extent to which extraneous light not passing through the negative is shut off from reaching the lens.

We are often asked what is the relative difference between the exposures required, when direct and reflected skylight respectively are employed; but on this point it is scarcely possible to lay down any fixed rule, as the exposures vary so greatly with circumstances. While in a general way the direct light will enable shorter exposures to be given, this is by no means the invariable rule; indeed, if sunlight reflected from a dead surface be employed extreme rapidity is secured, while the direct light from a cloudless, blue sky will produce a directly opposite result.

In using artificial light, whatever the source may be, some arrangement is necessary for diffusing it equally over the whole surface of the negative. This is a comparatively easy matter with small negatives, such as are most conveniently printed by contact, but become proportionately greater as the transparency is to be reduced from a negative of larger dimensions, say 12×10 , when a condenser becomes, for the amateur, out of the question. With rapid gelatine plates no difficulty, however, exists, on the score of lengthened exposure, in so arranging the

light or a series of lights at such a distance behind a translucent screen as to secure its pretty even distribution, the negative holder and camera being arranged in front of this illuminated screen in the ordinary manner, precautions being as usual taken to cut off as much of the light as possible not passing through the negative. With gelatino-chloride or collodion emulsion plates, however, the exposures under these conditions are extremely protracted.

The subject of development will be dealt with subsequently.

At length we have before us the full details of the dry collodion process spoken of by Dr. Hill Norris at the Birmingham meeting of the Photographic Convention of the United Kingdom in July last, and which created a species of sensation at the time. We shall here give merely an outline of its nature, as the full specification will be published next week. The silver salt is dissolved in the collodion, and the plate, coated with this, is immersed in a bath containing one or other of a mixture of haloid salts, some of which are insoluble in the ether and alcohol which form the menstruum in the collodion. After washing, the plate is subjected to the action of an alkaline bath (hydrate of potash), thereafter to a solution of gelatine, and, lastly, to a dilute solution of a soluble iodide or bromide, by which the silver bromide (or other haloid) is converted into the corresponding iodo-bromide. Modifications are described and full working details are given. The object of the whole is to produce a dry collodion plate of an exalted degree of sensitiveness. The specification is received at too late an hour to permit us at present making any observations on the discovery.

Among those who are about to migrate from this country for a time is Mr. A. L. Henderson, who leaves for Australia and New Zealand on the 5th proximo per *Oceana*, one of the P. & O. Company's ships. He purposes being absent from this country for nearly a year. Mr. Henderson has for some time experienced very indifferent health, which we hope will be fully restored by the voyage. When abroad he purposes visiting most of the leading studios of the southern world. His address will be—c/o Thos. Hodson, Norfolk Villa, Liverpool-road, Sydney.

Our contemporary, *La Nature*, contains in its last issue a very interesting article by its editor, M. Gaston Tissandier, entitled, *The Kite Photograph*, which is an account of a remarkable photographic feat well worthy of being recorded, from its containing the germs of a novel method of photography capable of useful applications. Our readers are familiar enough with balloon photography, and kite photography is not a new idea, its practical realisation having last summer been achieved by a clever amateur, M. Arthur Batout, whose kite is diamond-shaped, and measures over two and a half yards high. The camera is fixed to the edge of the wooden upright of the kite by a triangular support, and the "string" is attached to a kind of trapeze fastened to the kite in such a way as not to interfere with the field of view of the lens, which is an splanatic of 16 metre (about six and a half inches) focus, and used with the full aperture. The exposing shutter is of the simple guillotine pattern worked by two india-rubber springs, and is so arranged that when the exposure is made a little scrap of paper is loosened, and flying in the air indicates that the view is taken. The actual release of the shutter is brought about, not by electricity, as might be expected, but by the burning of a slow match which is lighted when the kite is flown. A further ingenious device consists in the mounting of a small aneroid barometer alongside of the kite. It is kept in a thoroughly light-tight receptacle, and the same match that releases the exposing shutter of the lens causes also a momentary uncovering of the barometer face, and imprints a record of the shadow of the registering needle of the aneroid. Thus a view is taken and a record made of the height of the camera at the moment. It is easy to conceive of the great use that could be made of such an arrangement in times of war, and the character of the negative obtainable is indicated by the accompanying engraving. It is a perfect plan in minia-

ture of the house and surrounding buildings of a farm taken at eleven o'clock in the morning of February the thirteenth last. We may add that the camera and lens weigh 1200 grammes, or about two pounds and a half.

At a meeting of the Academy of Sciences at Paris, on the 11th instant, a paper was read by Paul Poire upon the use of sulphite of soda for development. The abstract given in *Nature*, from whose pages we extract the information, is not explicit, but in its incomplete form is suggestive. "Numerous experiments carried out by the author with a solution of sulphite of sodium, and pyrogallic acid as a developing bath, show that the best results are obtained when the sulphite is in the proportion of twenty-five per cent., with 1.5 gramme of pyrogallic acid added." We do not learn to what it is that the sulphite bears the proportion of twenty-five per cent., nor to how much solution the gramme and a half of pyro is to be added. We are further told that "the developer is slower, but more intense and clearer than when the sulphite contains carbonate; the bath may be used repeatedly, and preserved for months in corked bottles." We gather from this that M. Poire used no alkali or other accelerator but the sulphite itself, and it has long ago been shown in these columns that this was a practicable, if slow, process.

A TWENTY-FIVE per cent. solution, *i.e.*, one four ounces by measure of which contains one ounce of sulphite, is a saturated solution, and if 1.5 gramme is to be counted one and a half per cent., we should then have about the ordinary strength of a pyro developer made with a saturated solution of sulphite. Judging of our own past experience, we think that an image of printing might possibly be obtained in from a quarter to half an hour.

We would draw particular attention to the reputed keeping strength of this mixture. It is quite certain that the full power of sulphite is by no means understood by the majority of photographers. We recently described experiments we had been making to ascertain the best proportion to use this salt in ordinary alkaline development, and to that article we would refer readers interested. There is one point that may be further elaborated. If a solution containing sulphite three grains to pyro one grain be used, the gradual colouration will soon supervene, so that at the end of half an hour the developer used for several plates in one dish would be too discoloured for comfort. If the large proportion of twelve grains to one be used, the solution at the end of that time would be little discoloured if placed in an open measure and allowed to stand till next day, and would be quite free enough from colour to permit of comfortable development.

CONFERENCE OF THE CAMERA CLUB.

THE Annual Conference of the Camera Club was held on Tuesday and Wednesday in the house of the Society of Arts. The attendance was fair, although scarcely up to that of previous years. Captain Abney presided on both days. The following is a list of the papers that were read:—

Tuesday, March 26, at 2 p.m. Conrad Beck, *Depth of Focus*; J. Brett, A.R.A., *The Relation of Photography to the Pictorial Art*; P. H. Emerson, *Science and Art*; Lyonel Clark, *A Comparison of Developers*; Captain Abney, F.R.S., *The Law of Error and Photography*; T. R. Dallmeyer, *Shutters*; G. Lindsay Johnson, *A Shutter Speed Measurer*. At eight p.m., exhibition of lantern slides in the theatre; slides from Paris, Vienna, American, and English societies.

Wednesday, March 27, at 10 a.m. C. H. Bothamley, *Chemical Changes from the Modern Point of View*; A. A. Common, F.R.S., *Irradiation in Astronomical Photography*; A. Dawson, *The Field of Photogravure*; W. T. Wilkinson, *Dry Plates for Photo-Litho and for Collotype*; A. Pringle, *Photo-Micrography*; Captain A. M. Mantell, R.E., *Photography applied to Military Purposes*.

In the evening of Wednesday the annual Club dinner took place at the Holborn Restaurant, a large number of members and friends being present. Captain Abney presided.

CRYSTAL PALACE INTERNATIONAL PHOTOGRAPHIC EXHIBITION.—II.

IN our issue for January 4 for the present year we spoke of a new camera, possessing several novel and excellent features, which had just then been finished by Messrs. Watson & Sons, High Holborn, which we described as folding into a smaller compass, and being lighter and more portable than any other pattern we had hitherto seen. Since that time this new style of camera has been manufactured, and has received a distinctive name, "The Acme." Of this style there are several sizes in the Exhibition, ranging from half-plate up to 15×12. By the aid of diagrams we shall endeavour to give a description of it in detail. Commencing with the baseboard. This is fitted with a combined turntable and tripod head, which, although light, yet looks very strong, being made of metal, and turned accurately into the baseboard, as shown in the cut.

Fig. 1.

When fully extended, the camera presents the appearance shown in fig. 2.

Fig. 2.

One among the several features in this is, that the front and the back may be brought very close together, without the baseboard protruding to interfere with the angle of view, no matter how great.

Fig. 3.

This peculiarity is shown in fig. 3. As we have previously said, the portability of the camera and the saving in size is very apparent, espe-

cially in those intended for plates of the larger dimensions. The back has reversing frame for vertical or horizontal pictures, and also swings in both directions. The drawings show the mechanical features with sufficient plainness to obviate the necessity for further descriptions. It is admirably made.

This firm also exhibits a fine 24 x 24 camera, of their "Premier" pattern, mounted on a mahogany studio stand, which would have delighted the heart of Jabez Hughes could he see it, for it is an outcome of his original Archimedian stand, which has here been subjected to a high process of evolution. This one has a spiral rack and pinion for raising and lowering, the same that is usually employed in many microscopes of the higher class, the advantage of which is that the cogs of the wheel never leave the teeth of the rack, which responds to the slightest movement without any backlash, and works with perfect smoothness. The arrangement for tilting the camera is exceedingly perfect, an important feature when one considers the great size of the instrument. They also show a fine specimen of their ordinary studio cameras; this one being 15 x 12, with double swing backs, operated by rackwork. The dark slide is made with a roller shutter, and the interior of it is fitted with a mechanical carrier to suit every size of plate. Tourist cameras, detective cameras, universal studio cameras; tripods of every kind, both for tourists and cyclists; enlarging lanterns; shutters of various kinds; optical lanterns; various styles of lenses, with and without iris diaphragms, complete the summary of the Watson exhibit this year.

An attractive feature in the Polytechnic School of Photography is a sailing boat, designed and fitted for photographing in shallow waters. The boat, as a boat, is arranged in a tempting manner, but its *raison d'être* is a fixed stand, on the top of which swings a somewhat large camera, the level position of which is insured by a pendulum-like appliance, which hangs below and dips into a tank intended to be filled with some slightly viscid fluid, such as glycerine. This "School" also shows a variety of other useful photographic appliances, including specimens of illustrations of the silver-gold printing process, described last year by Messrs. Howard Farmer and H. K. Tompkins at one of the meetings of the Photographic Society of Great Britain.

Mr. A. R. Wormwald, of Sutton, Surrey, exhibits an enlarging apparatus, which he designates "The Al fresco." It may be roughly described as a telescopic baseboard, lengthening out to about 5 feet 4 inches, and closing to 2 feet. There is a camera at one end of the base-

Fig. 4.

board, with bellows of the necessary length in proportion to the size of the apparatus, and filled with screw winch for adjusting the focus. The bellows is provided with a sleeve, in which is inserted the hood of the lens of a smaller camera containing the negative to be enlarged. Suitable arrangements are made for illuminating the negative that is to be enlarged, and also for receiving and holding flat the bromide paper on which the enlargement is to be made, this being of a nature somewhat similar to a printing frame. We presume the name is given from the apparatus being made ready for use at any moment, no preparation being required. "The Archon" may be considered as the antithesis of the "Al fresco," being intended for the production of lantern slides by reduction from larger negatives. It is in all essential respects similar to the foregoing one, only the light is projected into the camera from a reflector placed at the large end; but its nature is shown so very plainly by the accompanying cut that no further explanation is necessary.

Fig. 5.

Under the general title, Photographic Apparatus and Sundries, The Photographic Artists' Company Supply Association, of Charterhouse-square, exhibit cameras of various classes, including "The

Empress" and "The Standard;" lanterns, lenses, mounts, camera stands, studio furniture, with other appliances for use in the studio.

Among the exhibits of Taylor, Taylor, & Hobson, of Leicester, we observed the outcome of one feature which we have repeatedly mentioned with commendation, either as a desideratum or as having been accomplished by other makers of lenses. We allude to casket sets of lenses of various foci, all of which are capable of fitting one mount. One of these, for example, comprises a rapid rectilinear, mid-angle rectilinear, ordinary landscape, and wide-angle landscape; much ingenuity being displayed in bringing the zero of each cell—if such a term might be used—opposite to that of the scale by which the iris diaphragm is opened or closed. A battery of lenses of this class is, we need scarcely say, of great utility to the photographer. Besides these, this firm also exhibits quite a variety of landscape, rectilinear, portrait, detective, and other lenses and instruments. Shutters also form a section in their exhibits; in like manner do view finders, photometers, camera spirit levels, and appliances of a like nature.

Several months ago we described in these pages a most ingenious machine for engraving letters, figures, or designs, either on a flat plate or on the cylindrical surface of a lens mount. The machine in question also forms part of the exhibits of Messrs. Taylor, Taylor, & Hobson.

Among the various exhibits of Messrs. R. & J. Beck, Cornhill, we find several novelties, which include a stereoscopic hand camera, of different design to any we have hitherto seen. It takes pictures

Fig. 6.

on 6½ x 3½ plates. The shutter consists of a plate of metal passing through both lenses, thus opening and closing both by one continuous action. It is provided with Newman's pneumatic brake, giving exposures from one second to one-hundredth of a second, and with iris diaphragms worked by the same lever, which registers on a scale at the bottom of the box. Its general configuration is shown in the above diagram. Like most of the other hand cameras now in use, this can be used for time exposures on a tripod.

Their exhibit also includes rectilinear lenses of various degrees of rapidity, and a new series of autograph combination lenses. Cameras, stereoscopes, view finders, focussing glasses, shutters, lanterns, together with complete photographic apparatus, sum up the exhibits of Messrs.

Fig. 7.

Beck. We give an illustration of the mount for the combination series of lenses just referred to, to which a variety of lenses of different foci are adapted.

ECHOES.

My colleague, "Free Lance," in a late issue has some remarks on the subject of coloured screens in orthochromatic photography, from which, if I read him correctly, I must dissent. He says, "It is certain that no danger to definition need be apprehended from the use of screens" if a series of exposures are made in a reasonable time. I fancy the "printer" must have been "at work," for the meaning of the sentence as it stands does not appear very clear.

I scarcely think it can be meant that ordinary screens, *i.e.*, common glass, even of good quality, can be meant, for surely one who "knows his way about" as well as "Free Lance" does would scarcely make such an assertion: probably he intended to say "such screens," referring to the stripped collodion films just previously mentioned, in which case I quite agree that, properly used, little if any effect upon the defining power of the lens would be produced. But even then the thin collodion pellicle must be strained tightly over a suitable frame so as to present a perfectly plane surface, and this is not always an easy job.

The best coloured screen I have ever tried for the purpose, and I have used many, consists of a small disc of microscopic "covering glass" coated with stained collodion, and recessed into a piece of metal or card made to fit the diaphragm slot. If a perfect piece of the thin glass be selected, such as would be chosen for a slide to be used with high powers, the interference with the definition is, so far as my experience goes, quite undiscoverable, and I do not think there need be any surprise at the result. If such covering glass can be interposed between a test object and a high power without serious injury to definition, it is not likely to entail much trouble with the rougher work of the photographic objective.

Coating the lens itself with coloured collodion is effective so far as result is concerned, but objectionable on many grounds; but I have found even that method destroy the definition in one particular instance—that of a French portrait lens of very old make. A perfectly sharp image on the focussing screen became hopelessly blurred on the plate, while by racking it out of focus on the ground glass a well-defined negative was the result. No doubt the method of correction had something to do with the ease.

The *Flash Light Experiences* of "Guncotton" are interesting as proving that practical work can be done with very simple appliances, for surely nothing could be much simpler than the means he adopted for fancy dress ball portraits. This kind of experience is not, in actual practice, the plain sailing that previous arrangement and careful calculation apparently reduce it to, and on more than one occasion I have really pitied the poor photographer in his endeavours to face his sitters with an unruffled countenance in spite of untold worries. These worries would not, I should think, be lessened by the substitution of an ordinary guncotton "flash" light for the more carefully got-up electric installation, but the securing of a large number of negatives bears testimony to the feasibility of "Guncotton's" plan.

I formerly referred to this subject, and especially to Mr. A. L. Henderson's proposal to incorporate magnesium powder with celluloid, to which objection was raised in some quarters that the most explosive kinds of guncotton are not sufficiently soluble for the purpose. Since that I have tried an "idea" which may be of use, and seems to answer well. Thin Swedish filter paper was treated with cold concentrated acids to make the most explosive compound. When dry, two pieces of this were dipped into enamel collodion, quickly dusted with magnesium powder, and pressed into contact until dry. Result, a magnesium sandwich of excellent "flashing" power.

While on the subject of magnesium lighting, I note in a late issue, simultaneously with my mention of Mr. Henderson's proposed celluloid and magnesium mixture, the report of that gentleman's actual experiments in that direction. With regard to the objection raised at the meeting on the score of the dangerous character of the mixture owing to the admixture of chlorate of potash, I should judge, from my knowledge of the properties of celluloid, that the danger is chiefly imaginary, or, at least, that it is infinitely less than in the case of chemical mixtures containing that ingredient. Both celluloid and powdered magnesium may be regarded as practically inert substances chemically, the mixture being, in fact, a purely mechanical one, in which the particles of chlorate of potash are isolated and protected by the celluloid, which acts the part of an insulator.

Moreover, the mechanical admixture of the two substances in powder with the liquid celluloid or collodion would, I should think, tend to remedy the defect I alluded to last week, namely, the want of porosity; by breaking up the otherwise horny mass into a more spongy form, and by the provision of an additional supply of oxygen the combustion should be easy and rapid.

The question of comparative solubility is the point which strikes me as being of greatest importance, for, as is well known, the explosiveness of the different forms of nitro-cellulose varies almost inversely with its solubility. But this I think refers chiefly to the *rapidity* of combustion, which, in a manner, constitutes explosiveness. This characteristic is conferred upon the preparation by the employment, in the process of manufacture, of strong acids and a low temperature; the reverse conditions being conducive to the production of a soluble or photographic pyroxyline. But the highest of "high temperature" cotton, though it may not ignite with explosive violence, undergoes complete and rapid combustion when submitted to a sufficient heat; and in the comparative slowness of its firing perhaps serves its purpose—the thorough ignition of the magnesium—more perfectly than the more explosive kind, except when really "flash" exposures are required. In fact, when exposures of any duration are given I believe the less explosive kinds of guncotton will be found to answer best.

Another form in which nitro-cellulose can be conveniently employed for this purpose is in the shape of papyroxyline—"Chinese lightning" I think the toy shops call the little scraps of paper treated with nitro-sulphuric acid, and impregnated with a metallic solution to colour the flame. A drawback in employing ordinary guncotton is that if the powdered magnesium be thoroughly incorporated in its fibres, the mass is clogged and combustion retarded, a slight flash being succeeded by the slow incandescence of the bulk of the powder. On the other hand, if scattered only loosely over the pyroxyline much of the magnesium is blown away unburnt; and this is not only wasted, but gives rise to great uncertainty in the matter of the precise amount of light supplied. But by the substitution of papyroxyline the "flash" material is obtained in an equally combustible form, and with a far more extended surface, over which the magnesium may be sprinkled with any degree of thinness, so as to present as little retarding effect as possible on the combustion. By this means not only is the metal fully utilised, and therefore economised, but a large area of flame can be secured without the necessity for employing dangerous quantities of the explosive; and by suitably dividing the material the exposure may be varied to any extent. I will give Mr. Guttenberg the benefit of this suggestion for his time "train."

JUNIOR.

SITTERS AND THE COPYRIGHT IN PHOTOGRAPHS.

The latest exposition of the law of copyright in photographs is contained in the case of *Pollard versus Photographic Company*, which is reported in the current (March) number of the Law Reports. The case is of considerable importance to portrait photographers, whether professional or amateur, the essential facts being these:—The Photographic Company carry on business at Rochester, whither Mrs. Pollard went one day to have likenesses of herself taken from negatives made by assistants of the Company. Apparently when she sat for her likeness no special terms or conditions were mentioned between herself and the photographer, the transaction being one of the ordinary kind, thousands of which take place every day. Mrs. Pollard, who is presumably a lady of considerable attractions, subsequently found her physiognomy figuring upon and embellishing a Christmas card, with the superscription in leafy letters, "A merry Christmas and a happy New Year," and a copy of this card was exposed for sale in the shop window of the Company. Mrs. Pollard thereupon brought this action in the Chancery Division of the High Court to restrain the defendant Company from selling or publicly exhibiting copies of her likeness, and has succeeded in obtaining a perpetual injunction against the Company, who also had to pay the costs of the action. The judgment seems to be in accordance with common sense and natural justice, but the real interest to photographers lies in the arguments used by the counsel on either side, and in the remarks of the learned judge before whom the case was argued.

Mrs. Pollard, as is usual with most sitters, had not registered any copyright in her photographs, so that the judgment in her favour depends in nowise on the copyright acts, the case being decided simply on the common law rights of contract and property.

From the official report, which virtually now swells the law on the subject, it may be gathered that a photographer who has been employed by a customer to take a portrait is not justified in printing copies of such photograph for his own use, and selling and disposing of them or publicly exhibiting them by way of advertisement or otherwise, unless the customer has given him an "implied" or "express" authority to do so. Now the contract "implied" by law (there was no "express" contract) which was entered into between the parties when Mrs. Pollard sat to the photographer on this occasion was that he contracted not to use the negatives for any other purpose save for supplying her with copies. There is, therefore, a difference between a sitter who pays the operator for the photographs and the case where a snap shot results in a likeness secured. In this latter instance there is no contract implied, or express to take the likeness; there is no consideration for the work and labour done; there is no money payment made to the photographer, and, therefore, it may be presumed that if the portrait thus acquired does not transgress the rules and regulations of the law pertaining to libel, if it be not calculated to expose the person, for instance, to contempt or ridicule, the photographer may sell it or exhibit it. As one of the counsel argued for the defendant Company in this case:—"A person has no property in his own features; short of doing what is libellous or otherwise illegal there is no restriction on the photographer using his negative." From this it would appear to follow that where an amateur photographer gets a person to sit to him the artist has a right to exhibit the portrait because there is no contract that copies are only to be supplied to the sitter; there may even be no contract to supply him with copies at all, and, further, there is no consideration, no *quid pro quo*. The sitter sits to please the artist, the artist takes with the full intention of exhibiting the result if it prove satisfactory. That the amateur photographer intends to make some such use of the negative would be in the contemplation of both parties at the interview, though not actually mentioned. This is different from the case of Mrs. Pollard, where Mr. Justice North says:—"The phrase, 'a gross breach of faith,' used by Lord Justice Lindley in that case" (*Tuck & Sons versus Priester*) "applies with equal force to the present, when a lady's feelings are shocked by finding that the photographer she has employed to take her likeness for her own use is publicly exhibiting and selling copies thereof."

It was argued for the Photographic Company that inasmuch as the property in the glass negatives was in them, that they were only using their own property for a lawful purpose. In reply to which the learned judge observed, "But it is not a lawful purpose to employ it either in breach of faith or in breach of contract." This is the pith of the whole case—contract, breach of contract. Similarly there is a well-known case as old as 1753 (*Duke of Queensberry versus Shebbeare*), where the defendant was restrained by injunction from publishing a work, although a person had been expressly allowed by the owner to make and retain as his own a copy of the MS, which copy he had sold to the defendant; an agreement that the MS was not to be published was here implied. So also a student may not publish a lecture which he hears and takes down in shorthand; and the receiver of a letter may not publish it without the writer's consent, although he might argue, like the photographer with respect to his glass and chemicals, that the property in the paper and ink is in him.

Though, as has been said, this case did not go off upon any law of copyright, still, as a matter of fact, the copyright in a photograph, where the sitter sits to the photographer in the usual way of business, is in the possession of the person whose features are portrayed. There is an act (25 & 26 Victoria, c. 38, s. 1) which provides that when the negative of any photograph shall be made or executed for or on behalf of any other person for a good or a valuable consideration, the photographer shall not retain the copyright thereof, unless it be expressly reserved to him by agreement in writing signed by the person for or on whose behalf the negative is made; the copyright in the photograph shall belong to the sitter. Therefore, if a photographer wishes to make any other use of a sitter's photograph other than supplying copies to the sitter's order, he should get the sitter to sign

a written agreement that the copyright is thereby given to the photographer, who should pay something, even though a very small coin, for the same, and this sum should be mentioned in the agreement as the consideration.

But though the sitter paying for his photograph has thus a right to the copyright in his own features, by statute law he can bring no action against any one for infringement of his copyright until he has registered the same in the usual way at Stationers' Hall.

J. HARRIS STONE, *Barrister-at-Law*.

THE COMPOSITION OF HYDROQUINONE.

I wrote a fortnight ago that I had placed three samples of hydroquinone over sulphuric acid *in vacuo*, intending to leave them for a week in order to see if they gave up any water, and if so, how much. I should have given the result at the end of my article last week, but, unfortunately, I clumsily lost a minute quantity of one of the samples in removing it from the desiccator, and that one, of course, the most important. However, having now repeated the trial I can report.

All I have to say is, that after seven days, or, in the case of my repeated experiment with permanent hydroquinone, eight days, exposure over the strongest sulphuric acid, in a vessel partially exhausted of air, I have found absolutely no loss of weight, at least none that I can detect with the aid of a tolerably sensitive balance. The quantities operated upon varied from between six and seven to between nine and ten grains, and considering that the balance used will turn easily with the one-hundredth part of a grain, any moisture given up must have been at any rate less than one-sixth of one per cent. of the total weight—a very different proportion to that spoken of by Mr. Levy.

I said a fortnight since that if I found no appreciable loss of weight I should consider that the formula and composition of hydroquinone require revision. My reason for saying this was that if water were present simply from imperfect or insufficient drying of the crystals, or as a wilful adulterant, the treatment given could not fail to remove it, or, at any rate, the bulk of it. If present as water of crystallisation it might or might not be given up to sulphuric acid, but sublimation would be certain to separate it.

But since I wrote those words I have come to the conclusion that it is impossible that hydroquinone can exist in two states—i.e., anhydrous and hydrated—otherwise one would imagine that at least some of the numerous chemists who have examined the substance would have mentioned the fact. Yet such is not the case, nor is there the slightest doubt as to the formula and composition of hydroquinone. I can only conclude, then, either that the water Mr. Levy found was the result of imperfect drying, which does not seem likely from my own trials, or that he has come to an erroneous conclusion. So large a proportion of mechanically contained water is a very unlikely occurrence in these days.

If combined water were present it would be found in some definite proportions—so many equivalents or molecules. The figures given by Mr. Levy for white and yellow hydroquinone respectively, namely, 12.8 and 27.3 per cent., fall not a great distance away from the theoretical proportions of water that would be found in samples containing one and two molecules of water. These theoretical quantities would be a trifle over fourteen per cent. for the one and barely twenty-five per cent. for the other, and the approximation is sufficiently close to offer encouragement as an explanation of a discrepancy between results expected and those obtained, and I cannot help thinking that Mr. Levy has set down to "water" what must be sought for elsewhere.

Since I wrote last I have crystallised a quantity of hydroquinone from hot, dilute, sulphuric acid, and after drying thoroughly, have boiled, fused, sublimed, and otherwise misused it, without obtaining the slightest trace of the manifestations of SO_2 that can easily be got from the yellow crystals.

W. B. BOLTON.

THE LATENT IMAGE AND DEVELOPMENT: A THEORY.

At various times a great number of different theories have been proposed to explain the mystery of development. A few of these hypotheses are good or at least ingenious, and are to a certain extent supported by the facts; others are independent of such adventitious

support and stand alone, firmly rooted in the imagination of their inventors. I wish to add another to the already large number of explanations, hoping to be enabled to call up sufficient facts as witnesses to testify that the theory I am about to describe has at least as much, if not more, foundation than any of the others.

What the scientist calls an explanation can never in the nature of things be final. On the contrary, an interpretation of any set of facts always opens to view new and unexplored regions of nature. Science has been aptly likened to a sphere always growing, and so coming into widening contact with ignorance. It is common, though wrong, to speak of a fact or an experiment as having been explained, when in reality it is only classified along with others of its kind. We are often able to show that many phenomena hang together and must depend upon the same principle, without our being able to tell what that principle may be. This process of classification forms a very important step towards a true explanation, though it is not itself worthy of that name.

The operation known as redevelopment in the wet collodion process appears to me to furnish the key whereby to interpret all the phenomena depending on the "latent image." In this operation we make up a solution containing ferrous sulphate and silver nitrate. If these solutions are mixed in a concentrated state, a precipitate of metallic silver is produced immediately; if, on the other hand, both solutions are dilute, the precipitation of silver takes place very slowly, though it is eventually complete. The collodion negative before redevelopment contains all the detail but is very thin. The redeveloping solution forms a deposit of silver on the image and not on the clear parts of the negative; in other words, the silver is deposited on the silver already existing in the film. In some mysterious way, then, the presence of metallic silver assists the decomposition of the very unstable mixture of silver nitrate and ferrous sulphate.

A great number of similar cases are known to chemists, a few of which I may cite here; they are usually known as "nuclear" actions. The formation of crystals of any sort indicates that the substance crystallising has a preference, so to speak, for its own company, and can deposit itself more readily upon a piece of its own substance than elsewhere. Most substances will crystallise upon any sort of a nucleus, and the crystals start from specks of dust in the liquid or from the walls of the containing vessel. But there are other substances which will only crystallise when a nucleus of a particular sort is provided. Sulphate and acetate of soda are the best known instances, these substances being apparently almost incapable of crystallising until a nucleus of the salt itself is provided. Most metals when thrown down from solution show a tendency to crystallise. For instance, when a rod of zinc is placed in a solution of a lead salt, the zinc is dissolved and metallic lead deposited at first on the surface of the zinc. After a time points begin to grow out, the lead is deposited more rapidly on these points than elsewhere, so that they may grow to a relatively great length, say two or three inches, forming the so-called "lead-tree." A similar phenomenon occurs when a globule of mercury is left in contact with a strong solution of silver nitrate, the silver being precipitated in brilliant needles sometimes an inch or more in length. I cite these instances to show that metallic particles which are seeking a resting-place seem to have a preference for depositing themselves upon others of their kind. Although crystallisation is probably a chemical phenomenon depending on the combination of a substance with itself to form heavy molecules, or a polymer of high molecular weight, little is definitely known of the nature of the changes which accompany crystallisation.

For this reason it may be well to mention a few other chemical actions which start from a centre or nucleus of one sort or another. To this class belong many of those actions which are difficult to start, but which, once under way, go very rapidly. When a solution of chloride of calcium is mixed with sulphuric acid of a certain strength, no change is apparent for a few minutes or longer, then a cloud of calcium sulphate appears, and in a second or two the liquid may turn solid from the rapid formation of a dense precipitate. One other instance will suffice. Sulphurous acid acts upon iodic acid (not hydriodic), reducing it, and causing the separation of free iodine, or if starch be present in the liquid, of iodide of starch, which, as is well known, has a splendid blue colour. With solutions of ordinary strength this reaction appears to be instantaneous, but if the solution of iodic acid be extremely dilute, it may be mixed with the sulphurous acid and starch without any change being apparent for a time, which depends on the amount of the dilution. The reaction begins from some point in the liquid, and in a moment the whole turns of a magnificent dark blue. This experiment is in its way one of the prettiest in the whole range of chemistry.

I have dwelt thus long on these phenomena in order to show that

in the explanation I am about to propose I am not drawing on my imagination, but am attempting to class development along with a number of other phenomena, some at least of which are fairly well understood.

When bromide (or other haloid) of silver is exposed to strong light metallic silver is formed and bromine set free. Any one may convince himself of this by taking an ordinary gelatine plate into strong sunlight, when the odour of bromine will be quite perceptible. As to the sub-chlorides or bromides of silver, I consider their existence to be still questionable; the substance taken for sub-chloride of silver being, in many cases at least, merely a very intimate mixture of metallic silver with unchanged chloride. Now, if strong light can cause the separation of metallic silver in a visible quantity, it is obvious that feeble light may cause the separation of an amount of silver which is not detectable by optical examination. All developers are reducing agents, or substances which can cause the decomposition of a compound of silver with separation of the metal. Now at last we have all the conditions necessary: first, for the formation of an invisible or "latent" image; secondly, for its conversion into a visible negative. In the gelatine film there are particles of bromide of silver. When the plate is exposed to light, an extremely minute proportion of some of these particles is decomposed, and the number of particles in this way effected is proportional to the amount of light falling on the film. When the plate is developed the silver bromide is reduced, and this takes place first or most easily where there already exists a nucleus of silver to start the action. In other words, the greatest amount of metallic silver will be produced at the place where the light has acted most strongly. The reducing action of the developer is assisted and encouraged by the presence of minute particles (conceivably single atoms) of silver in certain parts of the film; at other places, *i.e.*, in the shadows, the action is not thus aided, the developer acts but slowly, and the operator has time to remove the plate from the solution before any perceptible reduction has taken place. This, then, is my theory in its outline. There are several minor points which are worthy of attention.

Although I have spoken of gelatine emulsion plates, it is self-evident that the exact same explanation will apply equally well to the collodion process.

The question has been often asked why gelatine plates are so much more sensitive than collodion. The usual answer is that it is due to the properties of the gelatine, which is much less stable than collodion, and, in fact, acts like a feeble developer. This explanation is at the best incomplete, for, if it were true, all that would be necessary to make collodion plates as quick as gelatine would be to use a developer so far stronger as to compensate for the indifference of the material of the film. I propose the following as an hypothesis, not as a full explanation:—The silver salt exists in the film in distinct minute particles, each of which must be supposed to consist of a very large number of molecules. Under the influence of light, points of metallic silver are produced in the particles of precipitate, and when the plate is developed these serve as nuclei, and lead to the decomposition of the particle in which they are situated. Now it is only natural that the range of the nuclear action should be bounded by the particle of silver salt, and should not extend through the material of the substratum so as to affect the neighbouring particles. This means then, that supposing light to produce a given amount of reduction in a number of different plates, and these to be all developed in the same way, the greatest amount of reduction will take place and the darkest image be produced in those plates in which the particles of silver salt are the *largest*. This is the reverse of what might be expected, as most chemical actions proceed more rapidly the more finely divided are the reacting substances. The increase of sensitiveness of an emulsion by long boiling may be accounted for in a similar way. Every analyst knows that freshly precipitated silver chloride is quite unmanageable, passing through even the thickest filter papers, and refusing to subside to the bottom of the liquid. On digesting the precipitate for a considerable time its particles aggregate and become much heavier, so that they settle down rapidly and are stopped by filter papers. The same process occurs, no doubt, during the boiling of an emulsion, only that in presence of the gelatine the process of aggregation would be much slower. The different physical condition of the sensitive salt in collodion and gelatine plates is readily explained by the different processes of formation; in the former case gradual diffusion into a film of extremely compact substance, in the latter sudden precipitation by mixture of liquids. We would expect to obtain a coarser precipitate in the latter case, and I believe it is true that the grain or texture of a gelatine negative is more pronounced than that of a collodion one. It seems to me possible that microscopic examination of plates prepared from an emulsion at various stages of the boiling process might

show whether there is, in fact, any increase in the size of the particles of silver bromide. The experiments would not be easy, and would require a very good microscope with graduated measuring apparatus, and even with the utmost care I should think it very questionable whether any definite result would be obtained. It is quite possible that though boiling might cause a real aggregation of the particles, the microscopic examination might lead one to suppose that the change was one of disintegration; such an appearance being caused by the breaking up of minute flocks of silver bromide, formed at the moment of precipitation. But all this is merely speculative; I have not made such investigations, and at the present see no prospect of having leisure so to do. I stated at the beginning that what I had to bring forward was only an hypothesis, and far from a complete, sound explanation, and now I may as well admit candidly that there are several peculiarities of sensitive films which I can by no means see my way to explaining by the theory described above. The chief of these knotty questions is the reversal of the latent image by over exposure. Another is the fact that gelatine plates are more sensitive when dry than when wet. This last may perhaps be explained in this way: The water covering the film may absorb the bromine rendered free by the action of light, and allow it to recombine with the silver and so destroy the latent image. It would not be difficult to "evolve" explanations of the reversal, but to that sort of thing there is no end, and I hesitate to enter on the war path of speculation, "for that way madness lies."

C. I. BURTON, B.Sc., F.C.S., F.R.S.E.

MERCURIAL INTENSIFICATION IN RELATION TO GELATINE NEGATIVES.

IN treating of this subject as related to the stability of collodion negatives in page 806 of the last volume of the *BRITISH JOURNAL OF PHOTOGRAPHY*, I promised to give the results taken in the same systematic way of a similar treatment of gelatine negatives since their general introduction.

Before entering on that subject, however, it may be mentioned that as one result of that exhaustive examination a series of experiments have been entered on and carried through which go far to show that the causes of the different varieties of fading there described were due principally to insufficient washing out of the mercury from the collodion film, aided by the latter being in some cases of a more or less porous nature than others. The more porous the film the more difficult, as a matter of course, is it found to remove the last traces of the soda, and these were found, or believed to be, the cause of the failures referred to.

In examining the gelatine series of negatives which have been produced within the last half a dozen years, I found, much to the annoyance of my professional friend, that the *quality* of the *clichés* in the gelatine series are by no means up to that of his collodion work. This is not so marked, say, within the last two years, but at the beginning of the gelatine period the difference is most marked. This may be most easily accounted for by the fact that the process was a comparatively new one and worked "per instructions." In such a case, as it must have been in many, if not most, of the professional studios, the results show that the work was pretty much hit or miss; in fact, if a very special subject had to be done, the old collodion was invariably resorted to in addition to the newly introduced gelatine dry plates, and, in most cases, to the disadvantage of the newer process, as might have been predicated.

Still the inveterate use of mercurial intensification is distinctly visible, and to attain rapidity with the collodion process the most attenuated and sensitive films were made use of, and the negatives, without the use of the mercurial intensification, would have been useless, would have been simply positives, with all the fine qualities of that class of work rendered permanent by the intensification referred to.

It was at this stage of the investigation that we found what I believe to be the true key to the failures with the use of the bichloride intensifier.

The spongy nature of the gelatinous surface of the (then) new plates far excelled that of the most porous collodion, and the necessity of (I had almost said) excessive washing, not being considered, we found the results to be as might have been expected, viz., a very large percentage of the plates which had not been looked up for, say, the last five years, practically useless as *clichés*.

The greatest curiosity was that not one of the collodion negatives taken as duplicates showed the slightest signs of deterioration. This may be accounted for by the comparatively slight deposit of reduced silver forming the image, and also as a secondary element, that very few of them had been subjected to the severe strain of a very large number of impressions being taken from them.

As we came down the series of negatives, it became evident that greater knowledge of the process, increased power of handling and management, came into operation, and this brought what is the one thing necessary: the capacity of producing the negatives without the need of intensification in any form.

It would be needless here to say that almost every form and kind of gelatino-bromide emulsion was made and tried with the usual averages of success and failures as there must be in all new, or newly attempted, processes; but this may be said now that, after thirty years' experience, and over twenty of that working the late Mr Lacy's (of, I think, the Isle of Wight) mercurial intensification, he has come to the very sensible conclusion that the best negatives which are got are those which need no intensification beyond the first development.

In reference to the failures—and they were many—it may be said that in every case that I examined, whether critically, chemically, or analytically, the cause of failure seemed to be the retention of the atoms of bichloride of mercury in the body of the film. In the case of the collodion, it must have been imperfect washing in the first instance, and exposure to light, air, and actinism in the second, allowing the imprisoned atoms to act at their own sweet will on the reduced silver, which had as yet been untouched by the intensifier; and in this instance the practice of showing the customer the partially blackened collodion negative, which showed as a fine positive, must have conducted to the large number of failures of the process.

With the gelatine plate this tempting method is impossible, but it renders it all the more imperative that the most thorough washing of this most insidious friend of a weak negative should be washed out of existence in every instance in which it is made use of.

To conclude, I may mention that the number of destroyed and deteriorated negatives taken by the gelatino-bromide process and intensified with mercury in the way I have described and gone over on the photographer's holidays, bad days for ordinary work show about an average of three to one against the gelatine; but while by no means liking mercurial intensification in this exhaustive examination, I must jot down that I believe the failures are more due to careless work than to the process itself.

W. H. D.

PHOTO-MICROGRAPHY.

[A Communication to the Camera Club.]

I AM sure that every one here will feel with me and sympathise with me in the difficulty that I have in properly treating the subject which is before us to-night, because although my audience is very large—for the rooms—and considering the subject fairly respectable, still I am well aware that there are three very distinct classes among you:—1st, Those who know nothing whatever about the subject; 2nd, Those who have certainly attempted the work which I wish to speak of; and 3rd, A class—the one I fear most of all—who know a very great deal more about the matter than I do. It is, probably, perfectly well known to all of you that of late years photo-micrography has come very markedly into public notice. There is hardly a branch of science which has not called in the use of photo-micrography, and for certain reasons the practice of photo-micrography has also been very greatly of late years improved. The results are very superior to anything that could have been produced a few years ago. Part of my task to-night will be to dwell upon what I conceive to be the reasons that have led to this improvement in photo-micrography, and to emphasise what I conceive to be the more critical points in photo-micrography to lead to the results that are being accomplished by some persons, now sought to be accomplished by all who give the matter their proper attention. In the first place, there are a great many members present who for many years attempted practical photography. If they try this photo-micrography they will find themselves very greatly in a position of advantage over those other gentlemen, who, however expert they may be as microscopists, are unacquainted with photography. I found myself, at my start, in a position of very much greater ease from the fact that I had been for twelve or fourteen years studying the *technique* of photography. My whole trouble practically lay in setting up an accurate image, and in, course, learning the means by which that accurate image has to be set up. When I got the image on the ground glass my chief difficulties were at an end. I said before that I believed that very great marked improvements have been made within the last two or three years in this department of photo-micrography. Most of you are aware that *photo-micrographs* have been of late used for books and illustrations of various kinds, where before drawings was the sole method of delineation. I believe myself that the day will very soon come when photo-micrography, with its indisputable accuracy, with its comparative ease and celerity of production, will take the place of any manual drawings. The chief points which have led to the improvements are:—In the first place, the science of *microscopy* has very materially improved within the last decade, or within the last five years, and the reasons which led to

this improvement are, first of all, the natural growth of the science; second, the improved optical arrangements which come within the power of the optician to manufacture, and of the microscopist to use; improved methods of illumination, by which I mean in particular the use of the condenser; and, lastly, I place great stress upon the introduction of a new kind of glass on which I shall make a few remarks later. In photo-micrography another great improvement has taken place in the matter of what is known as colour correct or orthochromatic photography. I only came into the microscopic world after a very great deal of this improvement, of which I have been speaking, had taken place. In other words, I entered after it began to be perfectly well understood by the most expert, and when it began to dawn on the less expert that a great deal of the path had been pursued in the wrong direction, namely, that of low-angled objectives. It is no business of mine to inquire what led to the low-angled lenses. By means of using these low-angled glasses the quality known as "penetration" was obtained. Another improvement, I say, was in the use of the condenser, and I believe (it was before my time) that the proper—the improved—use of the condenser was to a very great extent due to a gentleman who is present to-night, Mr. E. M. Nelson. Some still believe in narrow-angled objectives, but not very many use the sub-stage condenser in the way it used to be. I may just say a very few words upon the matter of penetration. [Illustrated on blackboard.] The quality known as penetration, if it exists at all, consists in bringing two objects which are one behind the other to a focus on one plane. This is an absolute impossibility according to the laws of optics. Two things in different planes cannot focus on the same plane. There are those who still stick out for the quality of penetration. They say that if the "disc or area of confusion" is less than one-hundredth of an inch the human eye is not able to judge of it. In photography this theory does not invariably hold good, because while on a large photograph, for instance, an area of confusion of one-hundredth part of an inch would not be any serious drawback, on a quarter-plate it would be fatal, and the photograph would be set down as unsharp and blurred. In microscopy we cannot afford to deal with any areas of confusion at all. We cannot have our image sharp enough. It is admitted by everybody that as the angle of the lens increases so the penetration of the lens diminishes; and, on the other hand, it is equally true that as the angle of the lens decreases, so also do the resolution and the definition of the objective; and as in microscopy and photo-micrography you want sharpness, there seems to be no argument left, no other alternative left but to sacrifice this mythical penetration, and to neglect it in favour of the quality which is paramount with us, definition, and in some cases resolution. Another point.—To correct aberrations inherent to single lenses, the method used invariably was to put together two glasses of different refractive indices in order that one might counteract the other; but until not so very long ago the two glasses used had indices in such a proportion to each other as only to correct the lenses for two particular regions of the spectrum, and not long ago two German savants, after, I presume, a great deal of experiment, succeeded in making another kind of glass which had a refraction index of different proportion to the other glass which is used in the objective, the result being lenses which, not only for microscopy but also for photography, gave us a more correct image than ever was got before. This is one of the great improvements which has raised the whole status of photo-micrography several degrees higher. The photographic side of the question I will leave till later on. With regard to the apparatus which I use myself, and which may be used by anybody, the requisite parts are a microscope and a camera. It is much more convenient that the microscope should be turnable down to the horizontal, and that the camera should also be horizontally placed, and it is necessary to have some arrangement by which the focussing adjustments of the microscope can be used at a distance. This exists in the apparatus there, which is simple, compact, and efficacious. [Apparatus further described.]

I consider it highly important, and certainly very convenient in use, that one should be able to turn the entire microscope and light right out of the axial line, examine the image, arrange and correct it, and then turn the entire system back to its position.

Then you have a real image thrown upon the ground glass of the camera, and once the image is on the camera screen, the matter becomes one of photography. The use of the sub-stage condenser is a crucial point. [Illustrated on board.] The point of the whole matter lies here. It is absolutely necessary, if you are to get a proper image, sharp and at its best, that the object shall be precisely at the conjugate foci of the objective and condenser. The image of the light is to be sharply focussed on the objective by the condenser. To equalise the field of light there is a temptation to put the condenser a little out of focus, but when the negative is got this plan will be regretted. For myself, if I get the condenser out of focus, I cannot get a thoroughly satisfactory image. If the illumination does not cover the field required, we must use a longer focus condenser, and that is the only way to get over the thing. I simply use a longer focus condenser, and the image of my plane is larger. I sketch here (diagram) a like makeshift apparatus I sometimes use for illuminating physiological and pathological preparations where no great resolution is required. A piece of very finely ground glass is illuminated by a bull's-eye, and practically becomes my radiant. It amounts to this: I am not able to accurately focus the condenser, but can very nearly focus it. I intend to try milk and water instead of ground glass. By a very slight

putting out of focus I get the field as I want it, and do not find the "loose practice" very materially spoils my photograph.

There is a general opinion that gelatine plates are unsuited for photo-micrography. I quite appreciate the idea that there is in this, but I think that the idea is slightly erroneous. Objectors to the gelatinobromide plates say that the image on rapid plates is too coarse in grain to be of use. It is coarse in comparison with wet collodion and slow gelatine plates, but the grain is not, so far as I have found, damaging; I have never yet known visible grain even in the highest direct magnification.

Specimens were once sent to me of the best diatom photographs I had then seen, done by wet collodion and subsequent camera enlargement, and I was challenged to prove equal results direct by wet collodion, or by any process except camera enlargement process. I went into the matter thoroughly, and the first time I tried with gelatine direct I found my results were every bit as good as with collodion and enlargement.

This is another point upon which there seems to be a certain amount of divergence of opinion. Some people think that uneven objects, as diatoms, are better done by taking negatives at, say, one hundred and fifty diameters, and enlarging twice in camera, than can be done by taking them at three hundred times by direct photographic methods. I came to a conclusion totally at variance with this. The trouble is got over as well—in certain respects better—by a direct magnification in the camera with the microscope lens, always with one proviso that you do not overstrain the objectives you are using.

I believe in high-angled lenses, the higher the better, provided corrections are good. Regarding condenser in the matter of angle, any microscopist will understand that there is not the slightest use in using a lens at high angle if you have not a condenser to match. A dry condenser of 160° I have always found to be ample for any purpose which I have required outside the domain of microscopic feats, such as test diatoms and infinitesimal flagellæ.

THE FOCUSING OF IMAGE.

A very great many different methods have been used; many ingenious, and I have never seen any seriously bad. The simplest is about the best. I have tried sensitive plates, fogged and slightly developed and intensified, and I have always come back to the old original business, which simply consists in a sheet of plate glass with some diamond-drawn lines on it; in my case the diamond-drawn lines consists of strokes divided into tenths of an inch, which divisions I use for approximate measurements of objects. It is exceedingly important, of course, to get focussing eyepiece accurately fixed; I "squash" a fly on the front of my plate-screen, and set the focus of my "Ramsden" or "Aplanatic" on the fly's wing.

As to correction of lens for cover-glass by tube length or collar adjustment, I find one system as good as another. There is no rule whatever for this correction. This correction is obtained by experiment alone. You have to sit down and alter the tube or collar until you get what you believe to be the sharpest image; that is where the real science of photo-micrography comes in. If photo-micrography is not an accurate science, it ought not to be used at all.

With regard, finally, to the photographic part of the question, the most marked improvement of late has been the introduction of colour-correct plates. We now find it easy to do objects which a few years ago would have been out of the scope of the photographer. I refer in great measure to the large and useful class of objects prepared with pathological and physiological stains. You may wonder when I say that the stain I prefer is one which consists of brilliant blue, red, and yellow. That is my pet stain. In every case I have used this treble stain in preference to all others. I have got to such a pitch now that, given any reasonable colour at all, so far as the photographic art is concerned, I usually succeed at once, but it is the rarest thing possible that I succeed in making a thoroughly satisfactory negative the first time I try. Sometimes I have tried twenty or even more times, and one object I have certainly done one hundred times, and have not succeeded yet. The stains met with in pathological and physiological work are logwood and eosine or other red. As a rule if logwood is deep enough, it may be photographed without a screen at all, but it is well to use an eosine plate. Bismarck brown has beaten me more often than any other stain. I never know what sort of screen I am going to use. It entirely depends on the tint. I am very fond of intensification of any kind. If intensification is to be properly carried out you must not let that plate see the light until it is absolutely fixed. I believe there is an invisible deposit after light action, but on intensification it becomes visible; that is of course a mere theory, but the conclusion that I arrived at.

With regard to printing, I find it unnecessary to say anything. Albumen printing is very satisfactory; chloride emulsion paper good; bromide paper the best. I almost invariably glaze my photographs. I may say in landscape work I do not like glazing photographs. It is very easily done.

In conclusion, I do not, of course, pretend to have nearly exhausted the subject. The chief thing often comes out, the real benefit got, in the discussion which follows. We have here to-night several men who have made a leading mark upon microscopy of the present day. Mr. Nelson is here, and also a gentleman who has made one of the most astonishing

and creditable discoveries with regard to diatom structures which have been made for many a long year.

ANDREW PRINGLE.

DISCUSSION.

MR. NELSON.—I have enjoyed the paper very much indeed; I take great interest in photo-micrography. Mr. Pringle has applied the microscope to his already excellent photography, while I have applied photography, through the kindness of Mr. Pringle showing me how, to my microscope. He has spoken of some microscopical matters in the first part of his paper which I might just allude to. One is the penetration of objectives. This has been a crux and bugbear. When I began I was beaten by this. I have had made for me low-angled glasses for penetration. Now I know better. I saw with practical experience they were a mistake. Now I know they were a mistake, and the reason is, there is such a thing as "numerical aperture." The numerical aperture of a lens of 180° is 1, or unity. The penetration of a lens is—mathematically must be—in the inverse ratio of the aperture. The penetration of a lens whose numerical aperture is one-half is one-fifth. Penetration varies at a tremendously greater rate according to focal length; the rate that the penetration varies in a microscopical lens is one upon the square of the focus. I have a tremendous pull over a man who is using a narrow angle. I want you to bear in mind that the focus of the lens has a greater effect on penetration than the aperture. The increase of aperture gives you an enormous pull by the increase of resolution. Mr. Pringle has alluded to the condenser and sub-stage condenser. One thing he did not lay much stress on, &c., the condenser used ought to bear some relation to the objective used. You must have a condenser for each lens; apo-chromatic system. We have not had them applied to telescopes and camera lenses. There has been a perfect revolution in the microscope. Professor Abbe has made the eyepiece enter into the construction of the microscope. This question of eyepieces and lenses is extremely beautiful and interesting.

A further discussion ensued.

ON DEVELOPMENT.

[A Communication to the Camera Club.]

How often we hear the merits discussed of the various kinds of developers, with regard to the amount of detail which can be obtained with them individually, or, rather, the sensitiveness of a plate with a certain developer. One man says he can get the most detail with ferrous oxalate, another with pyro-ammonia, another with pyro and potash carbonate, another with pyro-carbonate of soda, another with the use of caustic, potash, or soda, instead of the carbonates. Lately some have given the palm to hydroquinone, and so on. Seeing very great diversity of opinion, I tried some time ago to settle this question for myself, in hopes that some difference might be found considerably in favour of a particular developer, especially when we consider that in our choice we can actually deal with a total change in the chemistry of the materials. I therefore, as carefully as possible, began without prejudice, and during my experiments, when I thought there was any perceptible difference (I now only refer to sensitiveness), I tried, by alternation of formulae, to get the best results in all cases. To my great surprise I found all developers, including ferrous oxalate, all the modifications of pyrogallol acid with various alkalis and hydroquinone, exactly of equal value in the giving of detail. I must here state that the experiments were carried out with my own plates only, so that I cannot pretend to say that the results mentioned would occur under any circumstances; however, it certainly was remarkable that all kinds of developers gave the same results, and I should be inclined to gather from this, that any future increase in sensitiveness will be found in the plate rather than in the developer.

I have often heard my friend, Mr. Payne Jennings, use the rather pretty argument that, no matter how short the exposure, the image must be "all there" if you could only develop it. The little "if," as usual, settles the question. It is not much consolation to tell any one developing an under-exposed negative of an important subject that it is "all there." His reply could scarcely be entered on the minutes of this Club.

With regard to density of image, I also found that, provided the formula was arranged, equal apparent density could be had with all kinds of developers; I say apparent, because colour has, of course, a great deal to do with this. However, as there was no difficulty in getting sufficient density with all kinds of developers, I could not make a great point in favour of any one kind.

Having mentioned colour, I will digress for a few minutes to consider a very important matter with regard to it. What I am going to say is not new, but, as far as I know, much attention has not been paid to colour of image, excepting in a wrong direction. So that I may be clearly understood, I may mention that on many occasions I have had to make special plates for photo-lithography and allied processes where great density of image is required. I happened to call on a gentleman using these plates for copying line drawings, and found him using mercury intensification with all his work. I asked whether he could not get sufficient density by development. "Yes, certainly," he replied; "but we find that when sufficient density is obtained by development, the fine lines of the drawing are blocked up and detail is lost, so we prefer to stop development, and intensify by change of colour, without further deposit of silver to clog the

negative." For line work the difference in the two methods is so remarkable as to place the matter out of question. I have still further evidence on this point. At one time I remember Mr. Payne Jennings being very anxious to have some quickly printing negatives for a very large order, and I suggested the ferrous oxalate developer to prevent the yellow stain of the film. He used the iron developer for some little time, and, without giving the reason, told me one day that he found a blocking of detail in the high lights, and so he returned to the use of pyrogallol acid. To my mind the cause of the difference is simple, it being that a greater deposit of the silver compound to get sufficient density is necessary where the image is not of such a non-actinic colour. Colour of image is, I think, a matter of very great importance, and I hope that the members of this Club will give it their earnest attention. It seems to me that we ought to strive for a red or orange colour, and perhaps some means may be found of altering the colour of a negative simply, and thus do away with mercury intensification, which has several well-known defects against its use. To sum up the matter briefly, the more non-actinic the colour of the negative the better for its delicacy and good printing qualities.

The present general use of sulphites is, no doubt, mainly due to the desire for pretty-looking negatives. There is also an idea that sulphites in a measure prevent pyro stain to the film itself; this may be so when development is not pushed very far, but otherwise I think the remedy becomes worse than the disease, as the stain which occurs in instantaneous work when forcing development in the presence of sulphites seems less amenable to the action of clearing liquids such as solutions of alum and the various acids.

There is an objection to the use of sulphites, so far as I am personally concerned; it is the lengthening of the time of development, which takes place when sulphites are present in considerable quantity: this objection is also strongly complained of by professional portraitists. I confess to liking quick development, and I need scarcely say that when there are a gross or two of plates awaiting development, one gets rather tired of lovingly watching the slowly coming image.

Another substance, the meta-bisulphite of potash, has lately come into very extensive use as a substitute for the various sulphites. I would here mention that there is a very general mistake with regard to this salt, as it is confused with the bisulphite of potash. Even many of the large manufacturing chemists seem to be under the same mistake, as I have several times had the ordinary bisulphite given to me instead. The formula is quite different; the meta-bisulphite being $K_2 S_2 O_3$; the ordinary bisulphite being $KHSO_3$.

There is only one maker of the meta-bisulphite, the process being patented. According to the maker, it is a permanent salt, and does not change by exposure of the dry salt to the atmosphere. In my own experience I find it better to use than the ordinary sulphites, less of it being required, and in consequence there is not so much slowing action in development.

I dare say that many here have noticed with me that, with a given quantity of pyrogallol acid, the presence of sulphites has a destructive effect on the density of the image; it is perhaps for this reason that formulae for development containing sulphites are generally large in the quantity of pyrogallol acid recommended.

No doubt you have all noticed that the various carbonates when used alone, without the presence of a caustic alkali, considerably lengthen the time of development as compared with caustic ammonia; it is no doubt for this reason that amongst professional portraitists the use of the ordinary pyro-ammonia is generally preferred.

Hydroquinone is now becoming a great favourite, and deservedly so, on account of its comparative freedom from staining the film. Until recently its great drawback has been in the length of time required for development; but since the use of caustic potash with it, instead of the various carbonates, this trouble has been practically overcome. I tried a short time ago a formula by Mr. J. B. Payne, given by him in a communication to the Newcastle-on-Tyne and Northern Counties' Photographic Association. It is as follows:—

1.	
Hydroquinone	4 grains.
Meta-bisulphite of potash	4 "
Bromide of potassium	1 grain.
Distilled water	1 ounce.

2.	
Potassium hydrate	10 grams.
Distilled water	1 ounce.

Equal parts of 1 and 2.

This formula works very well; with some plates the bromide may be omitted.

I should like to say a few words on the development of landscape negatives, particularly with regard to obtaining cloud effects in the same plate as on which the picture is taken. We all know that as a rule the sky portion is over exposed, and very much so in comparison with the rest of the negative, and also that in many negatives we find clouds develop, showing all their detail at an early stage of development and then rapidly solarise away, leaving in the case of a thinly coated plate a thin, even sky portion, without detail and evidence of solarisation and halation in the picture, and in the case of a thickly coated plate, a dense

even sky portion that cannot be printed through, but as regards the half tones a better negative. Now, to get the best effects without double printing, development should be made as local as possible, the plate being washed along the sky line as soon as the sky is considered sufficiently dense, development being further carried on with the rest of the picture. Mr. Payne Jennings is very skilful with local development, and I pass round a few of his negatives to show what I mean with regard to it. A great deal may be done to help gradation in the extremes of light and shade in the make of the plate itself, and I may mention that I have to prepare a plate specially for Mr. Payne Jennings, containing a very large amount of iodide of silver. We all know how persistently Captain Abney has recommended the use of iodides in emulsions, and no doubt he is right where the best work is to be obtained. As a plate maker, however, I have to be chary in the use of large quantities of iodide, on account of the lengthened time of fixing and the alteration of colour in the image. For studio work, especially where large trade at small prices is carried on, I am afraid that a thickly coated, heavily iodised plate would be voted a nuisance, though better results would be obtained; but for landscape work, undoubtedly such a plate is by far superior where latitude of exposure, better gradation, and freedom from halation are required.

I should like to say a few words with regard to the various acids for keeping pyrogallie acid in solution. The best, I think, is sulphuric acid, and I use one drachm of the strong acid, diluted, to one ounce of pyrogallie acid. Sulphurous acid I find destroys part of the density-giving power. Next to sulphuric I should choose citric acid, though it has the defect that the citrates formed have a very softening effect on the film.

The use of sulphites for the purpose of keeping pyrogallie acid I consider bad. I find that where large quantities of them are used they create the very evil they are used to avoid, for instead of preserving the developer they destroy it—not that they may not prevent the oxidation of the pyrogallie acid, but in becoming oxidised themselves the development is stopped by the large quantity of sulphates formed; indeed, I have had, over and over again, solutions of pyrogallie acid rendered practically inert when exposed any time to the atmosphere.

A word on single fluid developers and I have done. I think them most unscientific. We all know how very thirsty is alkaline pyrogallie acid for oxygen, and, therefore, concentrated single fluid developers must soon spoil if in contact with air. All concentrated solutions of pyrogallie acid will keep indefinitely, whether acid or alkaline, provided the bottle be full and well corked, but the bottle cannot always be full, and then, of course, alkaline solutions must at once suffer. J. CADETT.

LORD RAYLEIGH ON EXPERIMENTAL OPTICS.

IV.

On Saturday, Lord Rayleigh delivered his fourth lecture on the above subject, and began by recapitulating that the mutual action of two streams of light produces the colours of thin plates; when those streams are nearly equal in intensity the result of their superposition depends upon the relative phases of the waves. In Young's language this was called "interference," but he, the speaker, was not very fond of that word, because from the point of view of the wave theory there is no superposition, and if that be called "interference," it is impossible to say what non-interference may be. If the plate is infinitely thin, then there is no interference, if the word has to be used. Interference is always measured by twice the thickness of the plate, and half a wave length must be added or subtracted, because the reflections from the two surfaces take place under different circumstances.

Every colour sensation is capable of being represented by various mixtures of red, green, and violet. Lord Rayleigh here drew attention to a colour-diagram, graphically representing the colour scale of Newton's rings. The colours of Newton's rings are rendered impure, he said, by a certain amount of white light superimposed upon them by reflection from the upper surface of the front lens. They are not the pure colours of the spectrum, and more especially in the red and green there is no approach thereto, but the blue and yellow are more nearly pure. By means of prismatic analysis the colours of the thin plates can be investigated more closely than by the eye. The lecturer here inserted a lens in a nearly parallel beam from the electric lamp, in the face of which lamp was a slit, and on the other side of the lens he placed a soap film, at such an angle as to reflect an image of the slit on to the screen; near the film, and between it and the screen, he placed a direct vision prism to analyse the colours introduced into the image of the slit by the soap film. In the same way he analysed the colours of Newton's rings, which experiment, he said, had first been performed by Young in the Royal Institution.

The colours of thin plates can be produced in another and inferior way, namely, by transmitted instead of reflected light; in the latter case they are reflected twice from glass surfaces, and in the former not at all; these transmitted rings are very faint, and the colours are hardly perceptible at a distance when an image of them is thrown upon the screen. When light falls obliquely upon a thin plate the relative retardation is less; when Newton's rings are observed obliquely they are dilated. Newton tried water and other substances in his ring experiments, but found that

they diminished the brilliancy of the colours; there was a loss of light, and the diameter of the rings was altered.

The colours of thin films sometimes came out upon a polished Daguerreotype plate when acted upon by iodine. Professor Sylvanus Thompson had lent him a piece of mica which exhibited the colours of thin plates with great brilliancy, as he would show them upon the screen. Old partially decomposed glass, such as is sometimes dug up with Roman remains, often displays the colours of thin films, and that, too, with some strength sometimes by transmitted light; in such cases, no doubt, a number of thin films are superimposed. It is easy to conceive that in the growth of insects a number of membranous films may be formed one upon the top of the other, with perhaps air spaces separating them, or perhaps some watery liquid; such combinations, supposing them to exist, would produce colours such as are seen upon the wing-cases of beetles, and upon other insects and living things in the organic world.

Newton, in his advocacy of the emission theory, devised periodic fits in the motions of particles; these fits were a kind of ghost of the real wave.

MR. MUYBRIDGE AT THE ROYAL INSTITUTION.

LAST Friday night Mr. Eadweard Muybridge lectured at the Royal Institution before the largest auditory, so far, of the session, the theatre being quite full.

Mr. Muybridge said that seven years ago he had lectured before the Royal Institution on animal locomotion, and since then had spent five years of his life at the University of Pennsylvania experimentally investigating the same subject, including the motions of children. He had but a small fraction of his results to bring under their notice that evening. His camera had a series of twelve lenses placed near each other in a horizontal row; there was also a thirteenth lens for focussing; thus twelve pictures were taken, and in rapid succession. A curtain shutter was used in the exposures, drawn down by an indiarubber spring. He did not state the focal length or nature of the lenses, or the size of each original negative. The shutters were released by means of electro-magnets governed by a wheel commutator, which would send twenty-four pulsations of electricity to twenty-four shutters in one revolution; but, as a rule, twelve pulsations only were sent by means of each alternate contact piece on the circumference of the wheel, it having been found by experience that a series of twelve consecutive exposures is enough to reveal all the details necessary to be known in a continuous series of motions by animals. Sometimes twenty-four exposures were made in a second. Three of these twelve-lens cameras were used at once over one animal, to show its position from three different points of view at absolutely the same instant. The results of all exposures exceeding one two-hundredth of a second in duration were rejected, as being too long to give results deserving consideration. None of the pictures, he said, were procured to be better than those of an amateur; they were not presented as fine art photographs, even were photography itself a fine art, which he very much doubted.

He then proceeded to exhibit on the screen positive pictures of the positions taken up when in motion by the horse, camel, lion, mastiff, tiger, "coon," buffalo, ox, goat, and hog. Also of a sloth crawling back downwards with its feet grasping the horizontal branch of a tree above. The order in which it moved its limbs was the same as with the animals previously mentioned, and a child crawling on all fours moved its limbs in a similar order of succession. Pictures of the ass and elk followed. Once, he said, it was a disputed question whether a horse in galloping ever had all its four feet off the ground at once; he exhibited a picture of one with all its four feet well in the air, and added that after such a position it always comes down first upon one of its fore feet; to this rule there is no exception. He exhibited a picture of the fastest mare in the United States, taken while she was going at a speed of fifty-two feet per second; one of her feet, he said, must have been moving at no less a speed than four hundred feet per second. He exhibited several series of pictures of a horse walking, trotting, and galloping with a naked man on its back. He also exhibited a series representing the kick of the mule and the peculiarly vicious twist it gives to its tail while flinging out its hind legs.

He likewise exhibited a series of photographs of statues of all ages and kingdoms, to show how artists had represented the attitudes of animals; some of these were exceedingly faulty, others, especially those executed by the Greeks, were remarkably accurate. The earliest representations of moving animals, he said, were not to be found in Egypt, for the preglacial man of the south of Europe executed very fair drawings upon bone; he exhibited a photograph of one of these drawings representing a reindeer. Pictures of moving animals from sculptures on the tomb of Ti, in Sakkarah, from Assyrian sources, from the sarcophagus of Amathus, in Cyprus, from representations of the victories of Rameses, and from other sources were shown.

From an artistic point of view the finest pictures shown by him were some of those representing the flight of the cockatoo; they were quite as remarkable and pleasing, if not more so, than those of Anschutz, of Lissa, representing the flying stork. He also exhibited a series of pictures representing the flight of the vulture.

Our Editorial Table.

NATURALISTIC PHOTOGRAPHY. By Mr. P. H. EMERSON.

London: Sampson Low & Co.

THE author seems to have slipped off the rails even before he made a start with his book, for in the dedication to the memory of Adam-Salomon of Paris, he alludes to him as having been the first artist of acknowledged ability who was original enough to practise photography for its own sake—a mistake the author was not likely to have made had he made himself better acquainted with the past history of photography from the art side of the question. From the apparent studious care with which others who have made for themselves name and fame as photographic "artists" are ignored throughout, a suspicion is aroused that, had not the soul of the talented French sculptor taken wing, he, too, might have remained unnoticed in his pages.

In the introduction, the author takes objection to the terms "amateur" and "professional" as usually understood, believing it to be folly to apply the former to one who does not practise photography for his living, or the latter to one who gains his living thereby. He gives it as his dicta that "professional photographers are those who have studied one branch of photography thoroughly and are masters of all its resources." An amateur, on the contrary, according to this authority, "is a dabbler without aim, without knowledge, and often without capacity, no matter how many of his productions he may sell." Under which designation does Mr. Emerson consider that he himself is entitled to rank? Photographers, accepting the universally received definition of the term, relegate him, perhaps too unceremoniously, to the professionals, because he—very wisely, as we think—practises the art for money, although not necessarily for that alone.

Passing over all that Mr. Emerson writes concerning ancient Greek and Italian art, Egyptian art, Greek and Græco-Roman art, and art of a great many other nationalities and periods—passing over likewise many pages devoted to the phenomena of light—we come eventually to the technique and practice of photography. Here we find much to astonish and amuse, with a limited amount of solid instruction for the young photographic aspirant. In course of this department of his book the author says, "In our student days it was considered bad form to give a testimonial to a tradesman for publication. This is still bad form." Seeing that there is a good deal of testimonial-giving in the form of recommendation of certain manufacturers, and which is not very far removed from a mild form of touting, to be met with more than once in his pages, we might ask if our author would not have occupied higher ground had he adopted the considerations of his student days in this respect. And in the face of this, Mr. Emerson allows his publishers to utilise and publish such testimonials as he himself has received in the form of favourable notices of his productions.

An air redolent of the personal superiority of the writer to the vulgar herd of photographers pervades the book, and much that they do is offensive to him. In vignetting, for example—but we will quote: "Whoever introduced the practice of vignetting was no artist, and the dodge was evolved from a misconception of the aims of art or for commercial purposes. . . . The few photographic portraits that we have seen worth studying were certainly not vignetted. Mrs. Cameron did not vignette—she knew better. That people demand vignettes and pay for them is nothing to us; let photographers sell them if it please the childish and vulgar, but let them not be called works of art, for on the contrary they are certain indices of bad taste." In speaking of lenses and referring again to the lady just mentioned, our author says, "The only really artistic series of photographic portraits we have ever seen, namely, those by Mrs. Cameron, were taken with a rapid rectilinear. . . . Mrs. Cameron, though not an artist, had knowledge enough to see that the portrait lenses of the day were undesirable for her work." Mr. Emerson is imperfectly informed as to this, for Mrs. Cameron used for her portraits a French portrait combination, and one that was incomplete at that, for the back lenses had been laid aside or lost and the front only employed, and this without a stop. Previous to her death she had obtained a proper London-made lens, but not with that did she make the series of artistic portraits referred to.

In the chapter devoted to photographic exhibitions and the medal nuisance there is much with which some will be in accord. The author says, "The method of organizing these exhibitions is to get a list of patrons, generally a few of the 'classes'; a few photographers who are known, but whose fame more often than not is based on nothing solid and is ephemeral; and finally the names of a few artists may be used to conjure with. Numbers of medals are advertised, and all works must be sent carriage paid. The judges are then chosen, and in nearly all cases

they are utterly incompetent. No one can judge a work of art unless he be an artist." According to this, no one is competent to judge the quality of a beefsteak unless he be a butcher; of a glass of beer unless he be a brewer; or, to come nearer home, of a gelatine dry plate unless he be a plate manufacturer; in short, that "who drives fat oxen must himself be fat." But to continue: "The combined assurance and ignorance of those who accept what should be considered a serious office is laughable and lamentable. Is our exhibiting student, then, going to submit his work to men untrained in art? If he does, he will find it either unhung, skied, or passed over in the awards to make room for the pretty nothingness and false renderings of the craftsmen's ideal."

Mr. Emerson is a fluent and forcible writer, who shows considerable familiarity with the writings of artists; and we think it a pity he had not adopted in his book a tone that savoured somewhat less of grievance against his fellow "craftsmen," who are to be excused if they have failed to discover in his published pictorial works aught that would warrant the indulgence of any superiority over the mass of photographers. The price of the book is six shillings.

No. 5067.—"Improvements in Photometric Apparatus." J. METHVEN.—*Dated March 23, 1889.*

PATENTS COMPLETED.

IMPROVEMENT IN THE HINGE OF SHUTTERS USED IN DARK SLIDES FOR PHOTOGRAPHIC PURPOSES.

No. 14,696. WILLIAM WATSON, 22A, Church-street, Islington, London.—*October 12, 1888.*

THESE improvements consist in forming the hinge or joint upon which the "back" of slide falls over in such a manner as to perfectly exclude all light when the back is closed.

I construct the joint with a rebate about alike in size on the abutting portions of the shutter. I place these together in such a manner as they form together a continuous groove (and not after the manner in which they are ordinarily put together so that the projection of the one part fits into the recess of the other part). Into this groove I fit a continuous piece of any suitable material such as hard wood, or vulcanite fibre, or such-like material; the joints are then covered with jane or similar material after the ordinary manner.

IMPROVEMENTS IN PHOTOGRAPHIC TRANSPARENCIES.

No. 1461. WILLIAM JOHN WILSON, 1, Chapel-road, Ealing, Middlesex.—*January 26, 1889.*

WHEN photographic transparencies upon clear glass are mounted for decorative purposes, it is usual to place behind the picture a piece of translucent, but not transparent, material, such as ground or imitation ground glass or opal glass, to form a background for the pictures which will permit the passage of sufficient light to render the details of the picture clearly visible, whilst preventing the effect of the picture being marred by objects situated behind the picture being visible through it. Such photographic transparencies have also been prepared directly upon ground or opal glass, which itself furnishes both the support for the picture as well as the necessary translucent but non-transparent background. Such ground or opal plates have, however, heretofore always been uniform over their whole surface, so that the margin (if any) beyond the edges of the picture has been perfectly plain.

The object of my invention is to provide such transparencies produced direct upon a ground glass, opal glass, or similar support and background, as last referred to, with an ornamental border or margin integral with the glass support, so that the transparency when "printed out," or printed and developed thereon, is set off and heightened in effect in a way not heretofore practised.

In carrying out my invention, the glass plate, instead of being uniformly ground or plain opal glass, has the desired margin or border already produced upon it in any of the ways hereafter referred to, that is to say, I use a piece of glass larger than the picture intended to be printed thereon, a portion of the surface of this glass at least as large as the picture being ground or otherwise rendered uniformly translucent but non-transparent, whilst the remaining portion of the surface is not uniform, but is occupied by an ornamental border or design, lettering, marginal lines, or other variation of the surface produced by alternations of translucent and transparent glass, or of coloured and uncoloured portions, or of designs in relief, &c. For example, by etching, embossing, grinding, sand-blasting, or similar process, or by the application of a matt varnish, the surface of the glass may be rendered translucent in some places and transparent in others. Or, a piece of flashed opal may have its opal surface etched off in places, leaving a clear marginal design or border. Again, a piece of white glass flashed with colour may have part of its coloured surface etched off and then ground for reception of the picture, the remaining portion

being either left uniformly coloured or etched in a clear design upon the coloured surface. In this way many variations of the general idea may be made.

I coat the sheet of glass previously ornamented in any of the ways above referred to, with a sensitive gelatine emulsion, the emulsion being applied over the whole surface of the glass or only over that portion intended to receive the picture, and upon this coated surface the picture is produced by printing out or by printing and development. The picture is then fixed in the usual way by dissolving out such portions of the sensitive salt, or salts, in the emulsion as have not been acted on by light, thus leaving the picture complete, with a translucent back and an ornamental margin or border.

Having now particularly described and ascertained the nature of the said invention, and in what manner the same is to be performed, I declare that what I claim is:—The manufacture and use of gelatine emulsion coated glass plates for the construction of photographic transparencies, the said plates having an ornamental border, design, lettering, lines, or other variation of appearance produced in any of the ways described upon the marginal portion of the plate before the same is coated, whilst the part of the plate to be occupied by the picture is uniformly translucent but not transparent, as specified.

IMPROVED APPARATUS FOR OPERATING THE SHUTTERS OF PHOTOGRAPHIC CAMERAS.

No. 1591. ROBERT EDWARD MATHER BAIN, 417, Olive-street, St. Louis, Missouri, United States of America.—January 29, 1889.

My invention relates to improved means for operating the shutters of photographic cameras, especially applicable to that class of shutters which swing past each other within a casing surrounding the camera tube, each shutter having a circular opening which coincides with that of the camera tube when the shutters are at half stroke.

Each shutter is formed with a curved slot through which passes the pivot pin of the other shutter, and with a short straight slot. Through the last-named combined slots of the shutters and through vertical slots formed through the front and back of the casing passes a pin, the whole operating so that on the full vertical movement of the pin in either direction the shutters are opened and closed to the camera tube.

My invention has for its object to vary the speed of the shutters when opening and closing the camera tube for instantaneous exposure, and consists in two (or more) springs having different and alterable tension or force, and applied separately or collectively, to the actuating pin of the shutters, whereby the speed of the latter when opening and closing the camera tube for instantaneous exposure may be varied at pleasure; combined with devices for holding and releasing the shutters and for checking their movement when at half stroke or with the camera tube fully open.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

MARCH 26.—Mr. Leon Warnerke in the chair.

Mr. E. FOCKING exhibited a print on albumenised paper on which white spots had appeared after the lapse of four weeks, and he wished to know the cause.

Mr. EDGAR CLIFTON thought that they were due to the paper.

Mr. ARNOLD SPILLER thought that they looked like bronze spots, but there was no bronze printing on the mounts.

Mr. W. E. DEBENHAM had known white spots to come on during the washing, and thought that he had perhaps traced them to particles of mortar falling on the prints.

Mr. WILLIAM BEDFORD said that coke dust would cause spots.

Mr. FRIESE GREENE said that he had a few experiments to bring before the meeting on "the electrical energy of different developers." He took a very sensitive needle galvanometer, and dipped the ends of its two fine-wire copper terminals in a solution sometimes of pyro and sometimes of quinol; when alkali was added to either, there was a momentary deflection of the needle.

Mr. DEBENHAM pointed out that when the alkali was poured over one terminal there was a deflection in one direction, and when he poured over the other there was a deflection in the reverse direction.

Mr. ARNOLD SPILLER remarked that it is well known that electrical action is always set up during chemical combination, and that as the pulsation set up before them was over in a moment, no proof was given of electrical action during development.

Mr. DEBENHAM remarked that if the developer were mixed first and then applied to the plate, the plate would develop, but no deflection could be obtained.

Mr. SPILLER thought the results to be outside photography.

Mr. CHAPMAN JONES said that until platinum electrodes were substituted for copper ones the experiments were not of scientific value, and even then they

would be outside photography unless it could be proved that photographic developers had some properties not possessed by solutions not developers.

Mr. GREENE said that when one terminal was touching a sensitive film in a developer, small deflections went on during the time of development. Extemporised gold and platinum electrodes were then tried, but with the means thus at command it was not certain that the copper wires also did not touch the liquid. Eventually Mr. T. Sebastian Davis agreed to carry on some experiments in the matter with Mr. Greene, and to report the results to a future meeting.

Mr. WILLIAM ENGLAND exhibited prints from negatives taken by the flash light at meetings of the Photographic Society of Great Britain and the London and Provincial Photographic Association. He thought the chief defect of the magnesium lamp to be that it did not work quickly enough; it gave the sitters time to move.

The CHAIRMAN had never found it to be too slow; with that apparatus he had brought from the Continent, and exhibited before the West London Society, he could take objects in motion.

Mr. FOX SHEW said that what was wanted was a large flame and a small quantity of magnesium.

Mr. DEBENHAM pointed out that in Schirm's lamp only three-quarters of a grain of magnesium was used, and that Dr. Eder had drawn attention to this remarkable fact.

Mr. JOHN SPILLER had pleasure in bringing before the meeting some remarkably interesting specimens of early photography, which had been given to him by the widow of the late Mr. Hunt, author of *Researches on Light*; several of them were dated 1844. He exhibited early calotypes, also foxy-coloured untinted prints taken on plain chloride of silver, still in excellent condition. Among some samples of chromotype was one taken by means of chromate of mercury, representing oak leaves, in which the image was about as good on one side of the paper as on the other. Many of the prints were by processes of which he could find no record, including one process called "the energiatype."

Mr. EDGAR CLIFTON interposed that the energiatype process was described in Bingham's *Photogenic Manipulation*. A sort of continuing action of light operated in the matter.

Mr. SPILLER continued that he had also a photograph consisting of letters on glass initiated "T. G.," which he supposed to be by Thomas Gaffield, who obtained such photographs by a year's exposure, allowing the light to discolour the glass itself. The print from this negative was taken in one minute. On the glass negative the letters were colourless on a purple background.

The CHAIRMAN had a plate-glass window in his house which had turned to an objectionable green. He believed that the glass was not so green originally.

Mr. SHEW exhibited a walking-stick stand of bamboo in which the two other legs of the tripod were of hickory and packed inside the cane portion.

Mr. ENGLAND said that it was remarkably firm for a stand of that class.

The CHAIRMAN, after measurement, said that its height in use was thirty-seven inches.

Mr. SHEW next exhibited a simple changing back in which no bag was necessary, nor any shields for the plates.

Mr. A. COWAN remarked that Mr. Wellington had invented one with the same motion, but his plates were backed.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

MARCH 21.—Mr. A. Cowan in the chair.

Mr. J. R. GOTZ was elected a member of the Association.

The HON. SECRETARY read a letter from Herr Julius Mayer, of Breslau, about the magnesium flash-light apparatus of Herr C. C. Schirms.

A question from the box set forth that it having been stated to that Association that the best lantern condenser for the lime-light was not the best for the oil light, the questioner would like the why and wherefore to be explained by diagrams.

Mr. T. E. FRESHWATER, who had made the statement, said that the condenser for the oil light should be of longer focus than the other one to get the best result.

The CHAIRMAN said that then it would take in more of the light from the flame.

Question: "Is the use of a combined toning and fixing bath to be recommended?"

Mr. WILLIAM BEDFORD replied that with the mixed toning bath there was sometimes a tendency to liberate sulphur. Once upon a time the bath was highly popular, and many old prints which had been toned in it had proved permanent, although the majority toned in it had faded.

Question: "What is the best form of shutter for long and moderate exposures?"

Mr. H. M. HASTINGS had found the Guerry shutter to be the best; it was always ready for use and no preparation required; its drawback was that it was too cumbersome.

Mr. J. J. BRIGNSHAW stated that in his hands it was not quite trustworthy, for it would stick sometimes, but it answered the purposes mentioned in the question.

The HON. SECRETARY said that that was also his experience.

Mr. BEDFORD said that a word might be uttered in favour of the double drop shutter improved or invented by Mr. A. Cowan.

Mr. C. H. COOKE then read the following paper on *Lantern Slide Competitions*:—

I wish to make a few remarks with respect to the lantern competition that took place here last Thursday. Now I consider that such a competition is a very good thing indeed, because it stimulates the competitor to do the very best within his power. Indeed, I wish that competitions such as the one in question or others of a similar character were more frequent, as I strongly believe they would urge amateurs and others to do much better work. I know that I took pains to produce the best slides that I could, but I may mention that I was dissatisfied with my results before they were judged; in fact, I never do anything but what I think that I ought to have

* The Energiatype is described in all Hunt's early writings. Succinic acid plays a part in the preparation of the paper.—ED.

done better, and always end with a determination to try and beat all previous efforts. Now I heard one or two of the members demur at the introduction of clouds, but you must remember that the competitors were authorised to do whatever they liked with the negatives in order to produce the most pleasing results, so long as they removed all traces of dodging, &c. I certainly think this is as it should be, and that it would be quite wrong to place any restriction upon a competitor possessing the good taste to introduce satisfactory clouds or to do anything else he might think proper to create a pleasing and harmonious picture. Speaking for myself, I should like to see clouds in every slide worthy of the name; and, further, I am strongly of opinion that no landscape slide should be accepted for any competition without a cloud. Just imagine the absurdity of an exhibition of paintings without clouds. A painting without clouds is not, and never has been, considered complete; then why should a cloudless photograph be accepted as fulfiling any more than a painting? I feel assured that the time will come when no landscape photograph will be accepted at any of our exhibitions unless it is a finished production in this respect. It is not by any means an uncommon thing to see a good landscape picture utterly ruined by the white space where the clouds ought to be, and we know that it is often the practice of photographers to take the greatest care to stop out the sky when, perhaps, if they left it alone they would get a certain amount of tone, which would be much better than the crude white paper. I have often seen it stated that the clouds should be secured at the same time that the landscape is taken. I am not altogether of this opinion. It is sometimes impossible to get clouds for days together. No, I certainly think well-chosen clouds may be introduced into any picture without the keenest expert being able to tell whether they were taken simultaneously with the landscape or a year or two after. Unfortunately we often see clouds introduced into photographs where they could not be expected to appear; for instance, such as cumulus clouds, which are generally boldly defined but comparatively flat near the horizon. Clouds of this kind are often placed too low in the picture, but such mistakes might easily be avoided if the observer were to make notes of the clouds when taking the landscape, assuming there were any at the time. Artists make endless studies of skies accompanied with notes, and I consider this quite as important for the photographer as for the artist. Then, again, skies are frequently printed too dark, which gives spectators a notion that the photographer must take most of his views in stormy weather. I know it is very easy to talk about these things, but not so easy to carry them out, and I do not think much of the man who is continually telling you what you may or may not do; I have greater confidence in the executive who does the work and produces his results. Advice from such a person is generally worth listening to. Therefore I believe if we continue these competitions we shall find ourselves making greater progress every time. I very much feared my old friend, Mr. Wellington, and, as I expected, he was the successful competitor; but I may tell him that if these competitions are repeated I will strive very hard to beat him, and very proud I should be to do so, for I admit he wants some beating. With reference to mounting the slide, some people will mount most of their slides in a circular mask, ignoring entirely the composition. It is but few pictures that this style of mounting is suitable for beyond portraits. I have a preference for the rectangular-shaped mount for nearly all pictures, and I do not even see why the corners should not be square instead of the present practice of rounding them. I love pictures and take the greatest delight in trying to produce them, and I only wish that our photographic monochrome was more perfect, but perhaps improvements in this direction are not far distant. The object of my observations is with a view of inducing the members to continue these competitions from time to time, and if they do so I believe that those who may compete will find themselves trying their very hardest to produce work of the highest class, as I think there is nothing so conducive to put a man on his mettle as a trial of skill.

Mr. J. B. WELLINGTON moved that a small sub-committee be appointed to draw up some rules with regard to lantern-slide and other competitions.

This was seconded by Mr. HASTINGS and carried unanimously, after which Messrs. Wellington, Freshwater, Cooke, and Cox were appointed members of the committee.

Mr. WELLINGTON thought that some description of the process by which each successful competition slide was taken should be given, and that there should be a slide competition once every two months during the winter season.

The Hon. SECRETARY thought that the operator had more influence than the process in producing the best slides.

The CHAIRMAN thought that all slides of landscapes should contain clouds in the sky.

The Hon. SECRETARY said that Mr. Green, of Berwick-upon-Tweed, had turned out in carbon the best cloud negatives he had ever seen. They could be printed from either side.

Mr. WELLINGTON remarked that commercial cloud negatives were always taken against the sun to get a striking effect, which often was not appropriate in subsequent use.

Mr. H. D. ATKINSON asked if better clouds could be taken by the interpolation of a yellow screen.

Mr. WELLINGTON replied that sunset clouds came out decidedly better on orthochromatic plates, but in no case was a yellow screen necessary.

Mr. BEDFORD stated that there was little advantage in using a yellow screen with ordinary plates.

Mr. W. H. HARRISON said that in one of the photographic annuals some time ago Mr. George Davison had written a useful practical article about taking cloud negatives; he had stated that persons who live in towns, in places where they must point their cameras upwards to get clouds, could not there get so appropriate a series of cloud negatives as photographers with an open stretch of flat country before them.

Mr. BRIGHENAW asked the best way to cut out mats for lantern slides.

The CHAIRMAN responded that by the wheel was certainly the best method.

Question: "What is the amount of advantage of a broad top in place of a narrow top to the camera stand?"

Mr. COOKE replied that a stand top but three inches in diameter had better be thrown into the river; the advantage of a good broad camera head would soon be found out in windy weather.

The Hon. SECRETARY stated that it was best to have the head of the camera stand as big as the base of the camera; the advantage of having a large head to the stand was very great.

The CHAIRMAN said that the more the tops of the legs had to be spread out to fit upon the head of the stand the better.

Mr. HARRISON had been informed by the engineers at Trinity House that with their concentric two-wick paraffin lamps a flame one and one-eighth of an inch in diameter would give the light of fifty candles. He thought such lamps, which were used on lightships, might perhaps be of utility in the optical lantern.

CAMERA CLUB.

MARCH 21.—Sir G. R. Prescott presided.

Mr. H. C. BOND, M.A., read a paper on *Photographic Exposure*. The lecturer enumerated and treated of five considerations upon which variations in exposure should depend, and proceeded to a careful analysis of several of the published tables of exposure, their use, and reliability.

A discussion followed, in which cap *census* shutter as a means of exposing, methods of counting seconds, timing shutters, continuing action of light on the exposed plate, and other points came in for attention.

The subject on Thursday, April 4, will be *Universal Formula for Enlarging and Reducing*, when Sir David Salomon will read a paper.

NORTH LONDON PHOTOGRAPHIC SOCIETY.

MARCH 19.—Mr. J. Traill Taylor (President) in the chair.

Mr. W. T. Corenton exhibited some stereoscopic slides made by the albumen process.

Mr. J. G. Hilton showed an album by Marcus Ward; the leaves were fastened in with small catches and were readily detached.

Mr. A. C. COSSON asked for a good method of preparing bright brass for photographing, to avoid patches of light.

The CHAIRMAN replied that a good method was to bring it from a cold into a warm atmosphere, and so cause moisture to deposit on it; a bright silver vase had been successfully photographed by placing ice inside.

Mr. COVENTON said that this method had been used to photograph cups.

The CHAIRMAN described how a stereoscopic slide could be viewed stereoscopically by holding it up perpendicularly, an eye being opposite to each half of the slide, and looking away to infinity. He also stated that in a binocular camera it is not necessary to bring the dividing partition right to the front of the camera; if it extends a short distance in front of the plate it is generally sufficient. Referring to telescopic photography, he said that the best results in celestial bodies were obtained without an eyepiece, but the image was of course smaller. A telescope could advantageously be used for terrestrial photography for obtaining photographs of very distant objects, a camera being fitted on to the eyepiece.

Mr. W. BISHOP said that for this purpose it would be better to take out the erector, as the image being reversed would not matter, and a great deal of light would be gained.

The CHAIRMAN said that if it were necessary to keep paper for silver printing a long time it could be sensitised in the usual way and instead of printing rinsed in distilled water to remove the free nitrate of silver. In printing, a pad of blotting paper fumed with ammonia should be placed at the back of the paper when it would print with great vigour.

Mr. J. G. HILTON asked if lantern plates could be prepared to print out and tone like sensitised paper, the glass being first albumenised and sensitised like paper.

The CHAIRMAN answered in the affirmative.

The next meeting will be on Tuesday, April 2, when the Hon. Secretary will give a demonstration on *Platinotype*.

SHAFTESBURY PHOTOGRAPHIC SOCIAL.

MARCH 22.—Mr. Stuart in the chair.

A number of cameras and other apparatus were exhibited by various members.

Mr. WILLS introduced a material made of a preparation of electrical insulation of paper as a good material for making stops.

Mr. BAKER exhibited a vignetter attached to the printing frame in such a manner as to enable it to be moved to any part of the plate required to be vignetted.

Mr. TOLLETT showed a view under which when closed was no thicker than an ordinary dry plate and about three inches by two inches in length and width.

The SECRETARY called attention to the smoking concert which is to take place on April 3.

WEST LONDON PHOTOGRAPHIC SOCIETY.

MARCH 22.—Mr. William England (President) in the chair.

Mr. Broughton exhibited a camera with a revolving turntable, the lens of which folded down flat for packing; the shutters of the dark slides were fitted with a new form of spring clip. Also a detective camera.

Mr. MILES showed a detective camera for 5 × 4 plates, arranged to hold six slides. The outer case was fitted with a finder and also a spirit level, which he considered to be an indispensable adjunct to a detective camera. He used a Ross' portable symmetrical of five inches focus, the diaphragm of which had been opened out to f-11. Working in this way he found he got very fine results. He also exhibited Shew's Eclipse hand camera.

Mr. Gale showed his patent Cyclone camera.

Mr. BLACKMORE explained a device whereby several lenses might be used on a camera without adaptors. The cross front was made sufficiently long to take three lenses. By simply sliding the front along and clamping, either lens might be brought to bear on the focussing glass. He also exhibited for Mr. March an ingenious mode of using small slides in a large camera. His camera was a half-plate, and when he wanted to take quarter-plates he slid a frame with grooves to take the quarter-plates into the runners for the half-plate slides.

Mr. J. D. ENGLAND had used the same device for several years, working quarter-plates in a 7 × 5 camera.

The PRESIDENT exhibited a light travelling tent, in shape like a triangular bag, and constructed to hang beneath an ordinary tripod. He had used it for many years when travelling abroad; it was light and portable, and folded up

into small compass. He then took a flash-light photograph of the meeting by a lamp constructed by himself.

The next meeting will be held on April 12, when Mr. Charles Whiting will read a paper on *Lantern Slide Making*, and a series of transparencies of Windsor Castle and Buckingham Palace, by Mr. King, will be exhibited.

HOLBORN CAMERA CLUB.

MARCH 22. Messrs. G. J. Shepherd, C. A. Burgess, J. Woodward, A. Pitman, J. Cook, Thomas and Mrs. Aldares Dear, and Mr. E. J. Tomlin were elected members.

Seventy slides were exhibited by the lantern.

Early in June Mr. E. Clifton will give an address on some current topic in photography.

WEST KENT AMATEUR PHOTOGRAPHIC SOCIETY.

MARCH 22.—Mr. Dresser presided.

Mr. Hamilton and Mr. Edgar were elected members.

Mr. Dresser exhibited a new pattern box for holding lantern slides. It was fitted with wood grooves to hold twenty-four slides, and neatly covered in dark cloth. It was brought out by Messrs. Fry & Co. for the small sum of 8s., and it was considered that it would entirely supersede the metal boxes at present in use.

Mr. Hawkins showed negatives of himself taken by himself with the flash-light process and prints from the same. They were pronounced excellent examples of the process. The disagreeable shadows so often visible by this process were in these cases entirely obviated by the use of reflectors. He also showed a negative and two prints, one developed with iron the other with quinol. The decision was in favour of the latter, but it was pointed out that the negative was unsuitable for bromide printing, being too dense.

Mr. PICKEL then showed negatives which had had varying exposures. He had heard that quinol was a better developer than pyro and did not fog an over-exposed plate in the same way. He had thought to test this with these three negatives, so had put them all at the same time in one large dish and had taken them all out together; he was then surprised to find the negative which had been over exposed so much thinner than the others.

It was stated that that would be the natural result; he should either have modified his developer for each plate or have left the longer-exposed negatives a longer time in the developer. He had previously stated that the plates were old. It was advised to obtain new plates and try again with the above modifications.

Mr. DRESSER gave it as his opinion that quinol was not a suitable developer for negatives, pyro being better. With quinol too much clear glass was obtained, and, however desirable this might be in a transparency, it was out of place in a negative.

Mr. Rushton contributed prints to the album.

The SECRETARY then gave the members a short address upon *Warm Tones on Gelatine Lantern Slides*. He said he was aware that some held the opinion that it was impossible to obtain warm tones on gelatine, while others, not going quite so far, maintained it was very difficult, and the results were always uncertain. Speaking of the negative, he advocated a full exposure, for the purpose of securing all available detail, and advised that development should not be carried too far. After describing the qualities of the plates he was in the habit of using, the lecturer proceeded to give a demonstration of the process, which was acknowledged to be at once simple and efficient, the resulting tone being all that could be desired.

The next meeting will be on Friday, April 5, on which occasion Mr. Rushton will deliver an address upon *Entarging*.

DEVON AND CORNWALL CAMERA CLUB.

At the last meeting, Mr. J. Pote in the chair, Dr. F. Woore, R.N., and Mr. Arthur Browne were elected members.

A paper by Dr. Aldridge was read, entitled *Picture Making, not merely Taking Photographs*. The subject of photography was treated throughout in relation to art, frequent references being made to the works of great painters and the general rules of composition. It was shown how a picture might, although true to the facts, be most artistic, whilst another, taken from a point only a short distance from the first, might be in every respect the reverse; how that the varying effects of light and shade, landscape, sea, and sky should carefully be studied; that a figure, boat, rock, or tree suitably placed might make instead of mar the picture. The paper was especially valuable in that it called attention to many rules known to artists (and Dr. Aldridge's paintings are well known in Plymouth) but frequently ignored, to their cost, by photographers.

Regrets were expressed at Dr. Aldridge's absence, and a vote of thanks was passed for his paper.

The next meeting will be on April 3, when Major Barrington Baker will make a few remarks on *Ficht Cameras*.

MANCHESTER PHOTOGRAPHIC SOCIETY.

MARCH 14.—Mr. Abel Heywood, jun. (Vice-President), in the chair.

Question box: "Are Beechey plates collodion-emulsion coated? Do they keep long? Has any member tried them, and with what result?"

In reply: Mr. JOHN SCHOFIELD said they were prepared with an unwashed collodion emulsion, then washed, and a preservative used; he did not know what the particular preservative Messrs. Rouch & Co. used, but stated that tanning, ale, or coffee would do. The plates would keep fairly well for a few weeks, and the results, as transparencies, were very similar to those made by Brooke's washed collodion emulsion.

The HON. SECRETARY had used a few of the Beechey plates as supplied by Rouch; they were excellent plates for transparencies. They would not, of course, keep like gelatino-bromide plates; one great advantage with them was that they could be reduced or intensified after development and fixing.

Question box: "A cutting from THE BRITISH JOURNAL OF PHOTOGRAPHY, *How to Test the Register of Dark Slides with the Focusing Screen*, was not thoroughly understood by the querist.

The HON. SECRETARY replied: In the course of his remarks he said that for ordinary landscape work it was quite unnecessary to go to very much trouble in this matter. It was quite sufficient to measure the distance from the ground glass to the lens flange, then to insert a plate in the same slide, put the slide in the camera, and draw the shutter, now measure from the plate to the lens flange again; any difference could be seen at once, and this method was quite good enough for practical purposes in landscape work.

Mr. H. M. WHITEFIELD said that would only apply to the centre of the plate, the corners might not be the same.

The HON. SECRETARY said in such a case the plate must be bent or twisted or the camera back would not be true with the camera front; it would be a vile instrument if that were so, but even in that case, a sixty-fourth, or a thirty-second part of an inch or more than that would make no practical difference.

Mr. W. WATTS exhibited and described the explosive gas tester recently introduced by Mr. J. H. Stewart.

Mr. J. H. FURNIVAL exhibited a very simple gas tester he had made; it consisted of a piece of quarter-inch brass tube about four inches long, with a stopcock in the middle, at one end was a fine nipple, on the other end a small indiarubber balloon about three inches in diameter (obtained from a toy called a squeaker). This indiarubber balloon in its normal condition was closed (at any rate, all the air could be squeezed out), now connect it up with the gas to be tested, when full close the tap in the middle of the pipe. Mr. Furnival said it was now ready for testing; if pure hydrogen were present it would burn at the nipple, if oxygen it would simply consume much faster the lighted taper he used; if mixed gas were present it would burn at the nipple so long as the pressure was maintained at the nipple, by the tightness of the indiarubber balloon, but as soon as the pressure was reduced as not to support the flame at the nipple, then a small explosion took place inside the balloon, but which was quite harmless.

A discussion followed and some highly interesting experiments were mentioned.

The HON. SECRETARY exhibited a few negatives taken on Carbutt's flexible films with prints from same; these had been sent to him direct from Mr. Carbutt. Next he exhibited a few others which he had taken himself; in one case a film and a glass plate negative taken under exactly the same conditions, and treated in development, washing, and drying exactly the same. There was very little to choose between them, but, as the Hon. Secretary observed, it would be rather unfair to expect the same quality of negative from a film the first he had ever tried of this kind, and with which he was not so familiar as he was with the glass plate used.

In reply to many questions Mr. CHADWICK said there was no trouble and no bother at all with these films; they developed like a glass plate negative, no after treatment was required; they were as hard in the water as they were out, and in drying he simply laid them on a table; they curled slightly, but that was not worth mention; they did not cockle or buckle.

Mr. WATTS introduced some matters of stereoscopic interest, and, through the Chairman, asked the Hon. Secretary if he would exhibit his stereoscopic camera and appliances at the next meeting.

The HON. SECRETARY objected on the ground that this matter was to a certain extent commercial with himself now, and in the position he held in the Society it must be against his ideas and his conscience for himself to introduce anything that might be regarded as "shop." (If he accepted the invitation from any other Society that was quite a different matter.)

However, after some arguments of the Chairman and many others, and at the unanimous desire of the members, Mr. Chadwick consented on the following conditions: that the next meeting be a "stereoscopic evening," open to everybody else, professionals, tradesmen, and amateurs alike, in which case he would contribute to the interest of the evening.

The suggestion was adopted. Messrs. Pollett, Coote, Schofield, Atherton, Benson, and the Hon. Secretary were elected to form the Outdoor Meeting Committee for the coming season.

DUNDEE AND EAST OF SCOTLAND PHOTOGRAPHIC ASSOCIATION.

The last meeting, which was held on the 20th instant, took the form of an exhibition of photographic views.

Councillor MATHEWSON, who presided, said that one of the objects of this meeting was to commemorate the discovery of the process of making pictures by the action of light.

Mr. J. W. McCALL gave a descriptive lecture pertaining to upwards of one hundred views, exhibited by Messrs. Valentine & Son, of various parts of North Africa.

PHOTOGRAPHIC SOCIETY OF PHILADELPHIA.

MARCH 6.—Mr. Frederic Graff (President) in the chair.

The SECRETARY reported the death of Mr. Emile Cresson, an active member of the Society, which occurred suddenly on the 2nd instant.

The Executive Committee presented a report proposing a plan for the selection annually, by vote of the members, of four "honour pictures."

The Committee on Joint Exhibition reported that responses from the foreign edition of circulars were beginning to come in, and a series of yacht studies by Messrs. G. West & Sons, of England, and also some pictures from Russia and Germany, had already arrived. Other foreign exhibits from English photographers were in prospect. The interest displayed by photographers in all parts of this country, not members of either of the three societies, was quite gratifying, many having expressed their intention of exhibiting.

A letter was read from Mr. W. E. Barrows, a member of the Society, as follows:—"Having occasion to use hyposulphite of soda for precipitation where freedom of foreign matter was important, we filtered fifteen pounds of that article through the accompanying filter. The hyposulphite of soda was purchased for photographic purposes from a manufacturer of established reputation in Philadelphia. Query: How many good pictures have been spoiled by the dirt in hyposulphite of soda?"

Accompanying the letter was a piece of filtering paper containing a large amount of foreign matter which had been filtered out of the solution. The condition of the filter seemed to indicate that Schoylkill water, in its most natural state, had been used either in the original preparation of the hyposulphite of soda, or in the solution which had been filtered. How far such impurities could effect photographic operations was not discussed.

Mr. THEODORE H. LUDKES read the following paper on the treatment of windows in connexion with interior work, recommending the use of flash-light compounds for obtaining the view beyond the windows, as well as the interior itself:—Any one who has made photographs of interiors has doubtless taken more or less interest in the window question, and tried in various ways to overcome the great difference in time of exposure necessary for the windows and the interior part of the room. These ways include shading and closing windows, inside and out, the local use of restrainers in development, and of vignetting in printing, &c. Wishing to try an experiment in developing, and having no plate exposed, I set up a small camera opposite a window when it was almost dark, and left it for ten or fifteen minutes while I prepared my developer. When the plate was developed, I found an image of the window sash, curtains, and shutters, and also of the trees and houses on the opposite side of the street, but nothing of the inside of the room. This suggested the possibility of getting a picture of the interior with the view outside on the same plate, and the flash light seemed the thing to do it with. The exposure by flash light may be done at the same time as the other if the lens will permit, or if it is not desired to have the outside in focus, or if it can be done after dark with a different stop and so have the whole picture sharp. The mode I found successful was to focus with the stop I intended to use for the flash, bringing the interior sharp, then inserting a small stop, and giving a suitable exposure for the outside about the same as if I was working out of doors—rather a full than an under exposure—preferably late in the afternoon, even after sunset; then capping my lens I inserted the large stop and left the camera closed till it was quite dark, when I uncapped it and fired my flash powder. The usual development seemed all right, and the result may be judged by negatives and prints shown. In THE BRITISH JOURNAL OF PHOTOGRAPHIC ALMANAC, 1889, there is a somewhat similar method described by an Australian correspondent, who uses, instead of flash light, ordinary gas with long exposure. Much might be said about the desirability of having in and outside both in focus at the same time, but that is a matter for individual taste and circumstances to decide. I think any one who cares to try this experiment will find it quite interesting, and another pleasure added to the many that photography gives us.

A film carrier, designed for use with Carbutt films, was shown by Dr. Hollingsworth, a visitor, who had designed it.

Mr. Earle showed a flash light devised by Mr. Edward M. Pini, a member of the Society. The flame was produced by a coil of wick about two inches in diameter, which was saturated with alcohol. Tubes of glass about two inches long, corked at each end, were loaded with about ten grains of powdered magnesium. A tube of magnesium could readily be inserted in a brass tube beneath the wick, the corks being removed as it was inserted. Pressure on a rubber bulb with tube connection forced the magnesium powder through a slit in the centre of the wick, producing a very brilliant light, which, by means of a cardboard reflector attached to the lamp, could be directed as desired.

A device for setting the shutter of a Scovill detective camera, obviating the use of the usual string provided for the purpose, was described by Mr. Pettit.

Mr. Graff showed a portrait transparency made in 1845 by Mr. Langenheim, of Philadelphia. The precise process used was not shown, though at that time the paper prints known as Tallotypes were in vogue. The transparency was in a most excellent state of preservation, though, apparently, some detail in the whites was lacking. It had a peculiar, warm, purplish-brown tone, which, as far as known, was the original colour.

[The transparency alluded to in the last paragraph was doubtless printed by the albumen process.—Ed.]

Correspondence.

Correspondents should never write on both sides of the paper.

WHITE HYDROQUINONE AND PERMANENT HYDROQUINONE.

To the Editor.

SIR,—In No. 1505 of your JOURNAL, Mr. Adolphe M. Levy publishes an article *On the Valuation of Commercial Hydroquinone*, and summarises the results of his analysis in the following words:—"The white sample, therefore, would appear to be the better of the two." It is his analytical tests only, and not any practical trials, that have lent him the justification to make this statement.

I have gone over the same ground, repeating Mr. Levy's experiments, with a view of judging how far his results were accurate. Both the white and permanent crystals were oxidised, as Mr. Levy had done, with nitric acid—the oxalic acid, the product of oxidation, being determined volumetrically with permanganate of potash. Schoonbroek, in his *Repertoire de chimie pure et appliquée*, 1861, states that in oxidising quinone with concentrated nitric acid at a high temperature, oxalic acid and picric acid are produced—a statement which, according to Mr. Levy, is also made by Schorlemmer.

This attempt at oxidation did not give any definite results. Pure nitric acid of specific gravity 1.4 was employed. It was first boiled in a flask, then evaporated to dryness in a porcelain vessel on the water bath, the operation being repeated three times with nitric acid of the same strength.

I. *White hydroquinone*.—0.5 gramme was made up after oxidation to 100 c.c.—10 c.c. of the solution required, at boiling point, in the presence of excess of sulphuric acid, 11.3 c.c. solution of permanganate of potash (of which 2.1 c.c. = 0.0045 gramme anhydrous oxalic acid) to establish the permanent colouration.

As Mr. Levy has found with tolerable certainty that the molecule of hydroquinone gives the molecule of oxalic acid, it follows that 2.1 c.c. solution of permanganate of potash = 0.0055 gramme of hydroquinone. Therefore, 11.3 c.c. solution of permanganate represent 0.03 gramme of hydroquinone, or 0.3 gramme in 100 c.c. This result is less by forty per cent. than the hydroquinone actually employed. The quantity of oxalic acid $[(COOH)_2]$ obtained for one gramme hydroquinone therefore amounted to 0.481 gramme, while Mr. Levy found 0.6 gramme*.

II. *Permanent hydroquinone*.—With 0.5 gramme under the same conditions, 12.4 and 12.3 c.c. respectively of solution of permanganate were required in two volumetric tests. Hence 0.325 and 0.322 grammes of hydroquinone, instead of 0.5 gramme, were found, and the quantity of oxalic acid obtained for one gramme of hydroquinone was 0.532 gramme. These two oxidations with concentrated nitric acid were carried out simultaneously side by side, and the results differed by 1.7 per cent. of hydroquinone.

In a second test of white hydroquinone a quantity of 0.5 gramme was again oxidised with nitric acid, the result being 0.19 gramme of hydroquinone. In these circumstances a second trial with the permanent was not made.

It follows from all this that Mr. Levy's estimations of the hydroquinone by the same method are valueless. That he obtained in repeated oxidations of the white crystals the same results may be an accidental coincidence. In repeatedly oxidising the permanent he did not obtain the same results; but, unfortunately, he does not give the details of his tests. In my trials, as shown above, the white hydroquinone exhibits the same irregular behaviour; therefore no conclusions as to the inferior value of permanent hydroquinone can be arrived at, for with the same duration of oxidation and similar conditions generally, approximately the same results are obtained with white and "permanent" hydroquinone.

As regards the oxidation of the permanent, I must mention that after the boiling with nitric acid a little barium chloride was added, in order to destroy the action upon the oxalic acid of the sulphuric acid (derived from the sulphurous acid of the permanent hydroquinone). The making up of the oxidised substance was done with sulphuric acid and water. Perhaps the difference in the results of Mr. Levy's tests with permanent hydroquinone is to be found in that omission.

Mr. Levy found or suspected sulphuric acid in the yellow crystals, consequently he ought to have neutralised it in determining the oxalic acid, as the latter would be decomposed by sulphuric at a high temperature into carbonic anhydride and carbonic oxide, which would render it impossible to correctly estimate the oxalic acid with permanganate. According to the length of time occupied in oxidation, the quantity of oxalic acid decomposed would vary.

From Mr. Levy's elementary analysis he says he concludes that the white hydroquinone contains one molecule and the permanent two molecules of water of crystallisation, and he is further induced to state that the white contains 87 per cent. and the permanent only 72.7 per cent. of pure hydroquinone. But as all data are wanting as to how he determines the water of crystallisation his conclusions are unjustified.

In order to discover water of crystallisation, the following two methods were adopted—(1) drying over sulphuric acid in the exsiccator, and (2) sublimation.

1. After having stood for twenty-four hours over sulphuric acid, neither the permanent nor the white showed any loss in weight.

2. *Sublimation*.—One gramme of each preparation was treated separately as follows:—The material was placed in a glass retort of the capacity of 1000 c.c., after thoroughly drying the apparatus, which I will describe. Over the retort was placed a bullet-shaped glass funnel, 25 centimetres high, to which was attached a glass tube of the same length having a bulb blown in it, and this was led into a weighed U shaped chloride of calcium tube. To protect the latter from outside moisture the apparatus was fitted with a soda-lime tube, through which, by means of a tube leading from above to the bottom of the retort, a gentle current of air dried over sulphuric acid was drawn by means of the aspirator, and during the passing of this current the hydroquinone was melted and sublimed, the operation in each case lasting upwards of an hour.

The tube, filled with perfectly dry chloride of calcium, increased in weight with the white by 0.407 gramme and 0.0066 gramme, or 0.468 per cent. of water on the average; and with the permanent, 0.003 and 0.0032 gramme, or an average 0.31 per cent. of water on the two trials.

These quantities are altogether too minute to justify any conclusion as to the presence of water of crystallisation.

Mr. Levy did not succeed in proving the presence of sulphurous acid in the permanent hydroquinone, but found one quarter per cent. of sulphur, originating, he thinks, from sulphuric acid, which he considers an im-

* The quantity of oxalic acid calculated by Mr. Levy at the end of his article on the oxidation of white hydroquinone is unimpeachable. If the molecule hydroquinone (110) give the molecule oxalic acid (90), one gramme hydroquinone must yield 0.818 grammes oxalic acid, not 0.673 grammes. It, however, 0.673 is the result of a hypothetical calculation based upon 87 per cent. of hydroquinone in the white commercial article, then Mr. Levy's test has still yielded 8.9 per cent. too little oxalic acid.

purity of the preparation. As he finds sulphur Mr. Levy doubtless tested with chromate of lead, instead of oxide of copper, which necessary circumstance he omits to state, though, if my supposition be wrong, his results must be corrected. Even on boiling three to five grammes of the crystals with water, there is a distinct smell of sulphurous acid, which latter also manifests itself by reddening moist blue litmus paper held to the mouth of the vessel.

The quantity of sulphurous acid being very small, it was measured in the iodometric manner in Bunsen's apparatus. In performing this operation it must not be forgotten that hydroquinone volatilises in the presence of aqueous vapour raised to the temperature of steam, and is also oxidised by iodine. Hence comparative tests were made.

I.—Ten grammes of white hydroquinone, boiled for three minutes in Bunsen's apparatus, reduced 0.00952 gramme iodine. The same quantity of permanent reduced during that time 0.06069 gramme iodine. To arrive at the quantity of sulphurous acid deduct the quantity of iodine reduced by the white crystals, and the result is 0.13 gramme sulphurous acid in the permanent sample.

II.—Ten minutes' boiling resulted in 0.122 per cent. of sulphurous acid, or an average on the two determinations of 0.126 per cent.

As sulphuric acid does not evaporate or decompose at steam temperature, and as the permanent reduces more iodine than the white hydroquinone, it follows (apart from other preceding proofs) that sulphurous acid is contained in the former.

Even from his own results, which, as proved above, are for the greater part erroneous, Mr. Levy had no right to conclude "the white sample, therefore, would appear to be the better of the two." Only the practical photographer can decide that question by valuing a preparation according to whether it performs certain required effects or not. But this he does not attempt from purely scientific analytical data.—I am, yours, &c.,

Dr. ALFONS LANGER.

Dr. H. Byk's Laboratory, Berlin, March 27, 1889.

CARBUTT'S FILMS.

To the Editor,

SIR,—As no doubt many will be using Carbutt's new films when it becomes known how good they are, I venture to send a description of a contrivance I use to facilitate washing them, the only difficulty I have had with them. The films are not quite stiff enough to stand up in the ordinary washing rack. I have overcome the difficulty in the following way:—I obtained some strips of thin zinc half an inch wide, and three quarters of an inch longer than the width of the film. Place a strip under the middle of a glass plate the size of the film, and bend over the two ends of the strip on to the top side of the glass plate. Take the films from the fixing bath, bend it slightly and slip the edges under the bent-over ends of the zinc strip, being careful to put the celluloid side next the glass plate. The glass with the film on it may now be stood in the ordinary washing rack; when washed stand in a draining rack, or, better, against a wall, till dry.

I find it impossible to wash these films in a dish, they stick so close together, also the celluloid is so hard that the edges are liable to scratch the gelatine if more than one is put in a dish at a time.

I would add, no other film I have come across can compare with these, they differ in no way whatever from glass plates in treatment, and I believe the high price compared with glass is the only thing which will prevent their having a big sale.—I am, yours, &c.,

The Hut, Ingatstone, March 26, 1888.

H. G. M. CONYBEARE.

VALUATION OF HYDROQUINONE.

To the Editor,

SIR,—I have just read Mr. W. B. Bolton's remarks on my paper concerning the valuation of hydroquinone, and if I am not taking up too much of your valuable space, I would like to reply to some of the criticisms made by Mr. Bolton.

I must own that I was not aware that only one make of hydroquinone was sold as "permanent," else I should certainly not have used the term in designating the sample which had been specially submitted to me by the Photographic Club. It must almost be remembered that I did not intend the paper for publication, and that it was only by request of the members of the Club that it was published.

I do not think there is any harm in my mentioning the name of the maker of the white sample. It was given to me by a friend as coming from Messrs. Hopkin & Williams. I do not think that this firm would be much benefited by any commendation that I could give.

Now as to water of crystallisation. I must state that I have been unable to find in any work on organic chemistry, and I have consulted most of the best, any mention of hydroquinone crystallising with water of constitution.

Still the figures yielded by the analysis remain. When I obtained the result of a first experiment, I thought that the discrepancy in carbon must be due to some fault in manipulation, and it is only after obtaining identical results from three different combustions of the same sample

that I came to the conclusion that the analysis must be correct. It seems strange that on calculating the excess of hydrogen into water, one should obtain in both cases the theoretical percentage composition of hydroquinone, or very nearly so.

Mr. Bolton's observation of what takes place during the fusion quite agrees with mine. If, therefore, the discrepancy of carbon is not due to the presence of water of crystallisation, the analyses of both samples as obtained from the combustions—the oxygen being determined as usual by difference—would be:—

	Permanent hydroquinone.	White hydroquinone.
Carbon	47.755	57.300
Hydrogen	6.745	6.196
Oxygen	45.500	36.504
	100.000	100.000

These figures do not yield any formula approaching that of hydroquinone, and I repeat that it appears to me at least surprising that the hypothesis of the presence of water of crystallisation should give results so closely agreeing with the theoretical composition, if this hypothesis is unfounded.

The results of this investigation on hydroquinone having, I must confess, rather astonished me, I thought I would examine some pyrogallie acid, of which I had just bought an ounce to be used in gas analysis for the absorption of oxygen. I hasten to state that there was no maker's name on the bottle and that the label simply stated "Pyrogallie Acid Resublimed." I made two combustions, of which I give the results side by side with the theoretical composition corresponding to $C^6 H^3 (OH)^3$.

	A.	B.	$C^6 H^3 O^3$
Carbon	59.230	59.132	57.160
Hydrogen	7.281	7.255	4.450
Oxygen	33.482	33.613	38.390
	100.000	100.000	100.000

Here again we meet with a considerable difference from the theoretical composition, though not as great as with the samples of hydroquinone. It will also be noticed that the carbon is found in excess as well as the hydrogen.

It strikes one that the product under consideration must have been modified in resubliming, and I may state that the crystals obtained in subliming hydroquinone are very different to any of the commercial samples I have seen. I do not think that, supposing hydroquinone to contain water of crystallisation, it will necessarily part with it when kept over sulphuric acid, as Mr. Bolton proposes to do. The formula of hydroquinone is most certainly accurate as it stands. The question is, whether the products that we buy under the name of hydroquinone are really that compound.

I am afraid that Mr. Bolton misinterprets my meaning with reference to the sulphurous acid point. An analyst simply reports on the sample intrusted to him. Mine contained no sulphurous acid, but sulphuric acid corresponding to .25 per cent of sulphur. I do not at all say that this is an impurity, but only that "it may be a simple impurity." The sulphuric acid may certainly be formed by the oxidation of sulphurous acid originally put in the compound. When I said that the "sulphur must be due to sulphuric acid," I meant the sulphur in my sample, and the sulphuric acid present in that sample.

It would be extremely difficult to compare one sample of hydroquinone or of pyrogallie acid with another with a view of determining its photographic value. It had struck me that chemical analysis might at least help to form an idea of relative value. The results obtained are certainly not very conclusive, as in all cases they differ from the admitted constitution of the chemicals, and, on another hand, I am afraid that it would be very difficult to say what proportion of the reducer contained in a developer is really utilised in developing the image. In my opinion the greater part is wasted in the case of pyrogallie acid.

I have to thank Mr. Bolton for his flattering appreciation of the value of my paper, and I am well pleased that it should have been criticised, since this will serve to bring more forcibly an important subject before the photographic world. Apologising for the length of my communication—I remain, yours, &c.,

ADOLPHE M. LEVY, C.E.

37, Bassett-road, Ladbroke-grove-road, W., March 25, 1889.

QUINOL.

To the Editor,

SIR,—A controversy is going on between the agents of the two German chemists as to the relative purity of their products of this reducer.

Having no interest beyond seeking for the truth, I beg to offer the following observations and experiments, taking the last first:—Having made up a matrix of about ninety ounces, I took two measures of this, five ounces each, and added an equal quantity of quinol from each maker. I found no difference in developing power, although from a rough, former trial I was inclined to a very decided preference to the quinol produced by Dr. Byk. Strictly, as Dr. Byk's contains some other chemical, it is presumable that in an equal weight from both makers the one would not

contain so much quinol as the other, but I doubt if it makes any appreciable difference. Again, I found that Dr. Byk's crystals, before they became finally dissolved in the matrix, turn white, also, if a few grains are crushed, as I crushed them, by one direct pressure (with my metal pipe stopper on paper on a board), they become white under the one direct pressure, although if ground up small to powder, as can be done, the white and yellow mix again. I left some of each maker's crushed and exposed to the air all night, also an equal portion from each dissolved in two equal quantities of soft water, leaving them exposed all night in open measures. In no case did I find any visible deterioration. Now I believe in the identical purity and power of each, although I am told numerous complaints have reached the agents of Dr. Byk that his quinol does not keep; but what does that mean? I never found that which he at first produced (white) deteriorate, and I have made up over one thousand ounces, a large quantity of it with his quinol. The complaint is so vague. If, for instance, persons will leave their chemicals, of any kind, unstoppered or uncorked, they must expect change; even stoppered it is not always preventable, and not intended it should be. What is the history of chemistry but change?—not certainly permanency. Its a misleading term. If it is meant that when mixed with other chemicals for development the mixture does not stand, that is more likely to be the fault of the matrix, which does not sufficiently control the reducing agent, than the reducing agent itself. Now I suppose nobody doubts that the yellow colour of Dr. Byk's production is due to sulphur in some form, either produced by SO_2 , H_2SO_3 , or H_2SO_4 .

Is it possible the crystals could be formed or dried in a vapour of burning sulphur, or evaporated out after being dissolved in sulphurous acid, or—? Unfortunately I am no chemist, but appearances seem to point to Dr. Byk's "permanence" being obtained by the coating of the crystals, and that it is therefore not a chemical combination, but really a mechanical enclosure so to speak, which adds to the cost of production, as is evident; but the commercial question ought not to be touched on here probably. Anyway, I do not think there is any ground for a dispute as to purity, and doubt if either the one or the other will prove his case. As I said before, I question if there is any benefit in this extra case as bestowed by the one and not by the other on this reducer.—I am, yours, &c.,

W. T. F. M. INOALL.

Greenhithe, March 23, 1889.

DETECTIVE CAMERAS.

To the Editor.

SIR,—On reading the communication from "Pylas" (in last week's issue) my first inclination was to look for the description of Aird's camera referred to. Unfortunately I have not beside me any JOURNALS prior to 1878. However, that does not much matter, knowing that Haddow's detective camera, described in the JOURNAL of March 15, must essentially differ from any form brought into the market in 1876.

This camera is undoubtedly one of the latest of all detective cameras—not a thing of the past, even though, from my description of it, there might apparently seem to be a similarity. It would have been much more satisfactory if "Pylas" had carefully inspected this new camera before tendering his opinion and assertion that it is simply a copy of one invented seventeen years ago. Mr. Haddow has, I believe, been requested to show his camera at the next meeting of the Edinburgh Photographic Society, to be held on April 3, when "Pylas" will have an opportunity of inspecting it and making further comment. Undoubtedly it is a little larger than some of the miniature dwarfs now sold, but this is counter-balanced by numerous advantages which it otherwise possesses. As each plate is exposed and automatically removed, an ivory indicator moves into position with the number of the plate (then in position) engraved thereon, so that there can be no mistake regarding the number of plates left in the camera, ready for use. When the exposed plate is removed it is entirely separated from those which are still unexposed.—I am, yours, &c.,

GASKIN WOOD.

6, St. Bernard's-row, Edinburgh, March 23, 1889.

DOES QUINOL CONTAIN WATER OF CRYSTALLISATION?

To the Editor.

SIR,—The analyses of two samples of quinol given by Mr. Levy in your issue of the 8th instant are so remarkable that I trust you will allow me to draw attention to their suspicious-looking character. Like Mr. Levy, I have been engaged in examining various samples of quinol (including that sold as "permanent") for the firm with which I am connected. In no case have I found a sample to contain water of crystallisation. Mr. Levy's figures look very imposing, no doubt, to the uninitiated, especially as he has taken the trouble of calculating his results to the third place of decimals (!), thus implying an accuracy of more than seventeen thousand times (!) as great as that to which he seems capable of working, judging from his carbon determination in the case of "permanent" quinol. The most accurate workers are generally the most modest in their claims. The most amusing point in Mr. Levy's paper is the agreeable manner in which the author's hypothesis of the

presence of water of crystallisation fits in with his results; but to be candid, it appears to me as if the reverse operation had been effected.

It will possibly interest Mr. Levy to learn that quinol may be completely oxidised to carbonic acid and water with less trouble than he seems to have experienced, and with more perfect results than he obtained with the combustion method. Potassium permanganate, the agent which Mr. Levy tried and abandoned, is the one which I employed; but as I have already published the details of the method (*Journal of the Society of Chemical Industry*, Vol. VI., pp. 98 and 269) it is unnecessary to describe the process here. With this method I obtained, with two samples of quinol which are constantly kept in stock by our firm, a consumption of permanganate corresponding to 97.6 per cent. and 97.8 per cent. respectively of pure quinol.

I might also mention that I experimented upon the oxidation of quinol by direct titration with permanganate, as indicated by Mr. Levy, and with more satisfactory results. In fact, if the acidified solution is titrated near the boiling point, a rapid and fairly accurate estimation of the value of a sample of quinol may be made. The reaction should be considered complete when a drop of permanganate is not discoloured after waiting twenty seconds. The quantity of permanganate used when this stage has been reached I find to correspond closely to the following ratio:— $\text{C}_6\text{H}_6\text{O}_2 + \text{O}_{10}$.

Of course these tests should be supplemented by others of a qualitative nature to ensure the absence of other bodies which reduce permanganate.—I am, yours, &c.,

I. H. SMITH, PH.D., F.I.C.

Mawson & Swan's Laboratory, Love Fell, Gateshead, March 23, 1889.

FRAMING PRINTS IN OPTICAL CONTACT.

To the Editor.

SIR,—In a late issue I observe F. R. Fisher inquires for a special mount for silver prints placed in contact with glass. The mounts he requires are supplied by Messrs. Marion & Co., 22 & 23, Soho-square, London, and are known as patent opalocrysts. Trusting this may be of service,—I am, &c.,

H. HEATHEN, C.E.

9, Corporation-street, St. Helena, March 23, 1889.

Exchange Column.

*. No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

Wanted, good rolling machine in exchange for gas bags.—Address, G. H. BRADSHAW, Bowdon.

A cabinet portrait lens (focus, nine inches; diameter, three and a quarter inches), by Lerebour; exchange for sewing chair with two or more backs.—Address, HORTON, Photographer, Caroline-street, Carlisle.

Will exchange a half-plate portrait lens by Lerebour & Secretan for a view lens by good maker; and a small gold watch, worth about 8s., for quarter-plate camera and lens with shutter.—Address, R. H. THOMAS, Rite Studio, Youghal.

Answers to Correspondents.

*. Communications relating to Advertisements and general business affairs must be addressed to "H. GREENWOOD & Co.," 2, York-street, Covent Garden, London, W.C.

All matters for the text portion of this JOURNAL, including queries for "Answers" and "Exchanges," must be addressed to "THE EDITOR," 2, York-street, Covent Garden, London, W.C. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.

WRIGHT.—We shall have an article upon the subject soon.

HENRY W. BENNETT.—Apply for permission to the Board of Works.

LEONARD BRIGGS asks for the best kind of acid for cleaning brass.—Oxalic acid.

Q.—Better hinge the ground glass to the camera, it is much handier than sliding it in or out.

DIAPHRAGM.—It is immaterial whether the calico be wetted or not, but had it been paper it would be necessary to do so.

WALTER.—But the print in optical contact with the glass so as to show a margin all round, then apply a suitable paint to the glass.

WATERHOUSE asks: "How can I make paper waterproof?"—Brush it over with a strong solution of castile soap, then when nearly dry paint it again with a solution of chrome alum.

TUNING BATH.—1. A toning bath made with acetate of soda requires to be kept twenty-four hours before using.—2. If you employ bicarbonate of soda instead of acetate it can be used as soon as made.

E. AUSTIN.—Seeing your lens worked well previous to it being scratched by the boy, we imagine that its imperfect performance is attributable to such scratching, but cannot definitely say unless we saw it.

H. H. WILLIAMS. Newman, 24, Soho-square, publishes a shilling work, *Reasons and Colouring as applied to Photography*, in which directions are given with great fullness, much more so than would be possible in this column.

A. H. B.—The transparencies are very nicely done. Subject to this one fault, that they show a lack of vigour, but this can easily be obviated in future by longer development. They have been handed to our publisher to await your instructions.

A. S.—To restore your printing bath, place it in a clear bottle, add kaolin, shake well, and place it in the sun; the colouring matter will be precipitated, leaving the solution clear. The best methods of preparing ready sensitised paper are held as trade secrets.

R. H. THOMAS inquires: "Can you tell me how blue opal pictures are made?"—In reply: Obtain from the Autotype Company samples of their blue pigmented tissues, and having selected the one that suits your requirement, print by the ordinary carbon process.

MECHANICAL PRO.—We know of no means by which the addresses of such a numerous body can be obtained other than by advertising in one of the daily papers. Even the *London Directory* fails to supply a complete list owing to so many conducting business in the suburbs.

H. JACKSON (Leeds).—No means can be adopted for hastening the drying of the gelatine other than heat and inserting the plate over a flat tray containing chloride of calcium. By screening or covering the drying box with one fold of calico there is scarcely much chance of dust entering.

T. E. G.—If the sulphite of soda is to follow previous treatment of the negative with bichloride of mercury the strength of the solution is immaterial. The article on intensification appeared in our issue of August 10, 1888. The number can be obtained on application to the publisher.

AS EDINBURGH FRIEND.—1. In connexion with the correspondence that took place relative to the camera mentioned by Mr. Gaskin Wool, Mr. A. Taylor has shown us one in which the plates are transferred from a reservoir above to a rack box below, these being moved in opposite directions by means of racks and a pinion.

R. J. COLEMAN says: "I have taken some stereoscopic pictures and send you two as a sample; can you tell me what is the matter with them? I cannot see them properly when viewed through a stereoscope."—In the samples before us the pictures are mounted wrongly; reverse the positions of the prints and they will appear with the desired effect.

HENRY SPINK. To silver copper without a battery, make a strong solution of cyanide of silver by adding cyanide of potassium in solution to nitrate of silver, also in solution; continue the addition until a dense precipitate at first thrown down is redissolved. The immersion of articles of brass or copper in this solution insures an instantaneous coating of silver; this the more especially if a slip of zinc be also inserted under such circumstances that it shall touch the article above, but not below, the surface of the solution.

C. WRAY PALLISER.—The markings in the plate appear to be caused by an impurity of the water. Try the following:—After taking them from the washing water remove all the surface moisture by means of blotting paper or by pressing in contact with a piece of clean muslin, then allow to dry spontaneously. Concerning the yellow stain on the transparency, it improved the effect so much that we were loth to attempt its discharge; however, we immersed it for a few seconds in a solution of bichloride of mercury to note the effect, when we found the stain was entirely removed.

T. McGUIRK (Tyron).—To take landscapes by a portrait lens remove the back combination altogether and screw the front one in its place, in this position a stop must be employed, the exact size of which can best be ascertained by direct experiment. By this arrangement portraits may also be taken in the studio, but the focus being now so much longer than that of the lens in its complete state a longer exposure is necessitated. A portrait lens to be employed for pure landscape work must be stopped down in a material degree, and this almost invariably entails the production of a flare spot in the picture.

CAPTAIN BARLOW asks for a formula for making emulsion for opal plates.—Let eighty grains of hard gelatine be dissolved in one ounce and a half of water, seventy-five grains of nitrate of silver being also dissolved in half an ounce of water, and in another half ounce of water twenty-one grains of dry chloride of sodium and a like quantity of citrate of potassium. To mix these, warm the silver solution and pour it into the gelatine, then add the soda and potash solution (warm), stirring all the time, and pour into a dish to set. Wash the emulsion by means of cold water. Next liquify it by heat and add two drachms of alcohol containing three grains of salicylic acid and one grain of chrome alum in a little warm water; filter, and coat the plates. This emulsion is very thin and will not keep, hence it must all be used at one time of coating. The plates are printed full out in the printing frame, no developing being necessary. After being printed, wash, and then tone in a borax bath; fix in hyposulphite of soda as usual.

L. D.—1. No alteration can be made in your lens that would confer in it the property you wish; both its construction and its focus are unfavourable to this end; you should exchange it for one of the so-called rapid class of doublets of smaller diameter and shorter focus.—2. A lens cell may often be removed from the tube by passing around it a belt of strong leather and holding the ends tightly in a vice, now grasp the tube and exert sufficient force to start the screw.

PHOTOGRAPHIC CLUB.—April 13.—Discussion on *Salted Paper*.

MANCHESTER PHOTOGRAPHIC SOCIETY.—At the last meeting it was resolved to invite matters of stereoscopic interest, both pictures and apparatus, for the next meeting, which is to be held on April 10.

THE first smoking social of the Liverpool Photographic Association took place on the 22nd instant, and was a great success. The programme, which was got up in a humorous style, being ornamented with photographic caricatures, comprised duetto for piano and violin, mandolin solos, and songs of various sentiments.

EXTENSION OF THE BURNLEY PHOTOGRAPHIC SOCIETY.—A meeting of this Society has been held, at which it was determined to include ladies, professional photographers, and all who take an interest in the science. Premises in Bank Chambers, Hargreaves-street, have been taken, and one of the rooms has been thoroughly fitted up as a dark room. It is hoped that the photographers of the district will avail themselves of the privileges thus offered.

NEW SOCIETY.—A photographic society has been formed at University College, the membership of which is open to all past and present teachers and students of the College. The annual subscription has been fixed at two shillings and sixpence, with an entrance-fee of the same amount. The meetings of the Society will be held on alternate Tuesdays during the session, and will commence at 5 p.m. Those members who desire it may have notice of the meetings sent to them by post on payment of one shilling in advance to the Secretary in addition to their subscription. R. T. Plimpton, Ph.D., Hon. Treasurer; W. North, M.A., Hon. Secretary.

A NEW form of sensitive flame has been introduced by Messrs. Thomas Fletcher, Warrington; it is produced by a special form of Argand Bunsen burner, which when lighted has inside of the ordinary flame a green ring of flame. When this burner is turned low the green portion of the flame disappears and the flame will then respond to ordinary conversation, and a loud clap or cough will cause it to go out. The flame emitted from this burner is of a very transparent character. We believe that this is the first time that an atmospheric burner has been used for the production of sensitive flames. It is neatly made of iron and brass and is sold for 1s. 9d.

A PHOTOGRAPHIC CLUB AT YONKERS, NEW YORK.—The Yonkers Photographic Club was organized on February 15, 1889, by the election of the following officers: G. Livingston Morse, President; Robert M. Reeves, Secretary and Treasurer; and the following Executive Committee: Salter S. Clark, R. Eickemeyer, jun., and F. W. R. Eschmann. The Club has forty members, and the roll is still growing. A very fine suite of rooms, overlooking the Hudson River and Palisades, has been secured in the Deyo-building, corner of Warburton and Wells Avenues, which are now being fitted up in the most approved style. Regular meetings are held on the first Friday of each month, and the annual meeting on the first Friday in April.

MR. G. J. CARTWRIGHT, writing from Buenos Ayres, remarks:—"Allow me to point out some errors contained in your list of photographic terms in Spanish, page 612 of THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for 1889. The language employed is Spanish, but the terms are anything but the technical ones employed by Spanish-speaking photographers and chemists. For instance, a photographic plate in Spanish, whether wet or dry, is 'chapa,' 'plancha,' or 'placa,' the latter being the word generally used, and never 'plato,' which means a plate to eat off, and which used in the other sense is ridiculous. 'Have you anything to declare?' ('Tiene v^d algo que pague derechos?'), contrabando is far too strong a word. Photographer is Fotógrafo, not Fotografiista. Dark room (Laboratorio). Nine (Nueve, not nueve). Focussing cloth (Paño negro). Focussing glass (Vidrio esmerilado ó mate). Stoppings (Diafragmas). Dish (Cubeta, and not fuente, which is used for eating). Chemicals (Drogas, and not químico, which means a chemist). Bromide of ammonium (Bromuro de amonía). Ferrous oxalate (Oxalato de hierro). Carbonate of ammonium (Carbonato de amonía). Bichromate of potash (Bichromato de potasa). Neutral oxalate of potash (Oxalato neutro de potasa). Soda is generally called by the same word in Spanish. Water is Agua, not agua. Glass measure—Medida de cristal para líquidos. Vaso means a tumbler.

ERRATUM.—We are sorry that, by a misapprehension, the article *Twenty Years of Amateur Photography*, published (p. 202) in our last, was made to bear the name of Mr. V. C. Baird as its author, instead of that of Dr. J. K. Tulloch, M.B., by whom it was written.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1509. VOL. XXXVI.—APRIL 5, 1889.

REDUCTION IN PRICE OF "THE BRITISH JOURNAL OF PHOTOGRAPHY."

IN view of the unprecedented success of THE BRITISH JOURNAL OF PHOTOGRAPHY since its foundation, thirty-five years ago, the proprietors believe the time has arrived for increased effort to meet the ever-growing popularity of the JOURNAL, and that this purpose will be attained most effectively, both for readers and advertisers, by the reduction of the price of the JOURNAL from 3*s.* to 2*d.*

This important reduction in price will doubtless still further increase the influence of the JOURNAL, and largely augment its already extensive circulation at home and abroad.

Subscribers who have already paid their subscriptions on the old scale will have the reduction placed to their credit or remitted, as they may desire, by the Publishers.

The Editor takes this opportunity of assuring the readers of the JOURNAL that the reduction of price above referred to will not in any way modify the general conduct and efficiency of the JOURNAL, which will be carried on, if possible, with increased energy in every branch of photographic research. The services of specialists in every department are secured as heretofore. This includes patent law as applied to photographic inventions; chemistry and optics; while in the departments of practical and theoretical photography, in all its branches, nothing will be left undone to ensure the continuation of the high position the JOURNAL has always maintained.

A commodious and well-appointed dark room has just been fitted up at the editorial and publishing offices, which will be at the service of any one who desires a suitable place for changing dry plates or for making experimental or tentative trials of developers. Friends passing through London to or from the provinces, India, the Continent, America, and elsewhere, will find this a source of great convenience.

The publishers desire us to announce that in accordance with the reduction in price, the subscription will be as follows:

ANNUAL SUBSCRIPTION.

(Post free, payable in advance.)

	s.	d.
United Kingdom and Channel Isles ...	10	10
France, Belgium, United States, Canada, Australia, New Zealand, Africa, Newfoundland, Germany, Portugal, Spain, Italy, Egypt, &c. ...	13	0
India, China, Japan, &c. ...	15	2

It also may be obtained from all booksellers, photographic dealers, and railway bookstalls, price 2*d.* Special terms to Photographic Societies.

DR. HILL NORRIS'S RAPID COLLODION PROCESS.

As announced last week, we are at length able to lay before our readers the full details of the rapid collodion process mentioned by its inventor at the last Convention at Birmingham, and of which the specification will be found in another column.

The name of Hill Norris was a household word on the lips of photographers of a previous generation, especially of amateurs, then almost the only users of dry plates; and five-and-twenty years ago the Hill Norris plates were practically, if not absolutely, the only commercial dry plates obtainable. It is needless to say that they were collodion plates, and, moreover, prepared with the bath, for they antedated collodion emulsions, which may, indeed, be said to have superseded them. The preservative employed was generally understood to consist of gelatine, and the resulting films when dry were thin, delicate, transparent, and extremely hard, while they developed easily and regularly with, for collodion dry plates, very short exposures.

It is scarcely surprising that the old users and lovers of collodion dry plates should sigh at times for the charms of their old favourite methods of bygone days; the rapidity of modern gelatine films has, however, hopelessly displaced the old style, though there are not a few, especially among the older workers, who would at once return to collodion if a rapidity at all approaching that of gelatine could be safely and practically attained.

To the more genuine workers of the old amateur type—the preparers of their own films and the makers of their own pictures—the question of trouble would form but a subsidiary matter, providing the rapidity combined with quality of result were obtainable. To the ordinary amateur, and for commercial purposes generally, however, it is absolutely necessary that the process of preparation be sufficiently simple to allow of the industrial production of the sensitive films on a vastly more extensive scale than was formerly the case. We may therefore consider Dr. Norris's process from these separate points of view, pending a thoroughly exhaustive trial of the actual working.

Looking at the early methods preferred by Dr. Norris, it is not surprising that on returning to his old love he should proceed on very similar lines. The method is, in fact, a "bath process," the film containing the silver haloids being entirely freed from soluble silver salts, and treated with an alkaline "accelerator," and either used wet or after the application of a preservative dried for future use. In carrying out this method the ordinary routine of the bath collodion process is varied inasmuch as the soluble silver salt—the nitrate, for instance—is combined with the collodion, while the bath consists of a solution of the different alkaline and metallic haloids required to

give the desired effect. In an alternative method, however, the collodion is prepared in the customary manner with iodides, bromides, and chlorides, possessing sufficient solubility in alcohol and ether, and the films so produced are sensitised in a bath differing from the ordinary silver bath on being saturated with certain double salts, namely, the iodo-bromo and chloro-nitrates of silver, and in containing an extraordinary proportion of free nitric acid.

The details of preparation present scarcely any further departure from the ordinary bath process, unless, indeed, it be in the length of time the film is to be immersed in the bath—"from fifteen to forty-five minutes;" and while we must confess to a feeling of disappointment at finding so little to encourage the hope for any exalted degree of sensitiveness, we feel convinced the general verdict will be that the process is not quite practicable for present-day commercial purposes. In expressing this opinion we need only compare the modern system of coating plates by machinery at the rate of several hundred dozens in the hour and the proposed revival of the old plan of individual coating, each plate requiring an immersion of from a quarter to three-quarters of an hour—not in one bath only, but in a succession of several separate ones.

It is clear, therefore, that, presuming the process to be capable of producing the rapidity and excellence of results claimed for it, it may perhaps be successfully and profitably worked by the more enthusiastic amateur or worker on a small scale, though the commercial plate maker would find himself at a loss to meet the demand created by the brief rush for the films as a novelty.

To briefly refer to the working details as set forth in the published specification, the first point that strikes us as worthy of comment is the composition of the collodion. This is directed to contain seven grains to each ounce of pyroxyline, made at a temperature "of about 200° Fahr." Now, speaking from an experience of many years in pyroxyline making for almost every possible purpose, we consider that such a temperature is impossible, and that, even if it were possible, the resulting pyroxyline would be useless for any photographic purpose. Those who have had any experience in the manufacture of "high temperature" pyroxyline for emulsion work, will know how delicate an operation it is at a temperature of only 170°—the highest, by the way, we have ever heard practically recommended—and there is a vast difference between that and the higher degree mentioned in the specification.

Then, again, the liquid contents of the collodion are abnormal in their relative proportions. Seven grains of pyroxyline are to be dissolved, we are told, in two drachms of ether and one drachm of alcohol, and the silver nitrate in eighty drops of glycerine and five drachms of alcohol, and the two solutions mixed. It is quite impossible, without actual trial, to say what will be the weight or volume in minims of "eighty drops" of a viscid liquid like glycerine, but we will assume that it is, at any rate, a drachm and a half, probably *very much* more. What, we will ask our old "collodion" readers, is likely to be the physical character of a film prepared from collodion containing seven grains pyroxyline, two drachms sulphuric ether, six drachms absolute alcohol, and *ninety minims of glycerine*? As ten minims of water would amply suffice to replace the above quantity of glycerine in dissolving the silver, the impracticable character of the formula is evident, but even then the proportion of three of alcohol to one of ether are prodigious.

So far as the substitution of a bath of haloids for that of silver is concerned we have nothing to say. Obermeyer,

amongst others, published only a few years back a process based on that principle, but it is doubtful whether any advantage was ever found to accrue.

Is not the partial conversion of silver chloride into bromide and iodide by means of the corresponding soluble haloids, and of bromide into iodide by similar means, calculated to give rise to a great deal of uncertainty, unless the bath employed contains a definite quantity of the halogen it is required to substitute, and *is allowed to exhaust itself*?

The employment of the alkaline accelerator, either with or without the addition of a preservative of gelatine, albumen, or similar substance, was at one time strongly recommended by the late Thomas Sutton, who in 1871 published it in pamphlet form.

Turning to the alternative or "acid" process, the employment of a silver bath, saturated with iodo and bromo nitrates, will appear to most of our old wet collodion readers a somewhat heterodox proceeding. The silver bath was always considered to be in its best condition as regards sensitiveness when new, becoming slower in action as it became charged with ether and alcohol and double salts derived from the films immersed. Yet here we have these same double salts added to promote sensitiveness!

Again, the nearer a bath approached neutrality, the more sensitive it was usually considered to be, the addition of acid promoting cleanliness of working, but reducing the rapidity. Mr. J. W. Black, of Boston, however, some fifteen or sixteen years ago, published a process in which a *very large* addition of nitric acid was made to yield rapidity. In Dr. Norris's process the same result is attained by the use of from forty to one hundred minims of dilute nitric acid of specific gravity 1.101 to each ounce of bath—equivalent to from eight to twenty minims of strong nitric acid of specific gravity 1.45 to the ounce.

For the present, space compels us to leave the subject, but we shall lose no time in practically testing the process, adhering, *as far as it is possible*, to the strict details laid down.

PRACTICAL CONSIDERATIONS IN STUDIO BUILDING.

III.

WE may now leave those structural considerations more essentially connected with outside influences, after dwelling for a short time upon a condition already dealt with—the existence of a lofty wall, or building, against which a studio may be erected. We have shown that when such a structure lies at the south end of the studio, it is of immense service in warding off the direct rays of the sun, and so avoiding excessive heat in summer, besides being free from midday sunbeams between lens and sitter; but a professional friend points out to us a still further benefit such a structure affords, which he has experienced to the full. Every photographer is aware of the evil effect upon the quality of his negatives through light from sky or clouds falling upon the lens, and the fastidious worker will not, until they are combated, attempt to obtain a negative where such conditions exist and are avoidable. Lens screens in plenty have been devised and are in use to prevent this access of light; but all require adjustment, according to circumstances, in places where more sizes of plate than one are used, and the lens power is not single. The gentleman we refer to points out that when there is a large building behind the sitter, it almost obviates the need of any screen of the kind, and any one who has worked under such conditions and then

builds a new studio without the advantage of a similar protection, although he use lens hoods, &c., may be excused for not discovering at once the cause of the occasional slightly foggy plates that he is almost sure to obtain at intervals. This is a point of great moment.

A lofty studio will of itself, but not entirely, unless of very extraordinary dimensions, tend to obviate the need for outdoor obstructions, and, from many points of view, a design which gives high walls will be very advantageous. Foremost in this way may be placed freedom from oppressive heat in summer time. A small studio is so quickly made hot that, unless a very complete outside protection from sun rays is devised, it frequently becomes insufferably close, while larger rooms, even with skylights of proportionately equal size, are far more pleasant. This question, however, touches so closely upon considerations of finance that we will not dwell further upon it than to point out one too frequently overlooked consideration, which is as follows:—The taking of groups, we may safely say, is now much more frequent than used to be the case, and the advantages of a lofty room are, for this work, of overpowering force. Thus, if any pretence whatever to selective illumination is attempted, and a completely "all round" lighting be not adopted, a dozen figures might easily be posed in a lofty studio without any striking inequality of illumination; but in one of lower proportions the illuminating aperture of the roof is of such varied proportions as regards the different individuals of the group, that while those on one side are in bright light, those at the further side may be in comparative darkness.

Following upon the height of the roof is the question of what its pitch is to be, and here practical experience tells that the mere question of shape of roof as regards its illuminating possibilities should not be the only consideration. Efficiency for purposes of portraiture must be the prime factor; but regard for it should not be allowed to obscure other matters of importance. Thus, though it is true that in winter time less photographing is called for than in the brighter days of summer, there yet is always in many studios a steady amount of work done in the depth of winter to which a heavy fall of snow may quickly put a stop. Other things equal, a steep roof will always be far more quickly rid of a snow covering than one of more gradual slope, and might at times be a matter of great importance. Of course all glass roofs should be so constructed that when a snowfall does lodge upon them it can be easily removed; but, as a matter of fact, we need scarcely tell our readers such facilities are the exception rather than the rule. "A man with a ladder" too frequently has to be sent for, and too frequently cannot be found; many a sitter has to remain unphotographed from this cause. This is, naturally, only exceptional, yet it should be provided against, if only for the possible chance of the frequent winter studio visitor, the sitter in "fancy dress," whose habiliments are usually only his for the brief space of two days.

We may here describe a plan for dealing with the difficulties of an inaccessible roof which we have seen, and that appeared to us eminently useful and practicable, not to say philanthropical. The glass roof was erected upon walls which went sheer down to the ground without a break for upwards of fifty feet, and to use ladders for roof work was difficult and costly, and workmen were rather chary of venturing upon this precipice, as they termed it. The difficulty was apt to become so troublesome, and the proprietor of the studio felt so great a responsibility for the safety of the workmen who had to clean, paint, or repair, that, with the consent of the neighbour whose

premises would be to this extent trespassed upon, he erected a narrow platform, protected by a handrail, outside the whole length of his studio, and from it there was no difficulty in getting upon the roof, and no trouble was in future experienced through unwilling workmen.

As an example, however, of the personal supervision which should be given to all work of importance, we may give our readers the personal experience of the gentleman who had this structure made. He entered into no contract, but gave instructions for a "neat and safe platform" and rails to be made. The platform was secured by bolts attached to large iron plates fixed on the inside of the wall, and the two lines of protecting rails were held by a series of iron uprights, which were further stayed to the sash-bars at intervals from their highest points. When all was finished, the proprietor himself went to test the safety and utility of the structure, and while talking to the workman who was engaged upon this "safeguard," leaned against the rails. "Do not do that, sir; it might give way!" Explanation being indignantly demanded why the money lavished on this means of protecting workmen should have been thrown away in the production of a worse than useless arrangement, it turned out that the rails, instead of being made of iron bars, were of brass gas-pipe, rendered still more fragile by being half cut through in tapping them for screwing the sections together! The brass piping made a larger bill to bring in, and so the original question of safety, and the whole purpose of the erection, was utterly ignored.

AN article by Mr. W. K. Burton on page 233, in which he treats of the elimination of hyposulphite of soda by alternate washes of hot and cold water, reminds us of the system adopted by the lately deceased veteran photographer, Mr. James G. Tunny, of Edinburgh. This experienced printer never considered that a print had been properly washed until it had received a thorough swishing with very hot water. Indeed, it stands to reason that, as a solvent, hot water must necessarily act with far greater rapidity and efficiency than water which is cold. Some photographers who are inexperienced remove their prints from the hypo bath before they are properly fixed, that is, before the double salt hyposulphite of silver has been dissolved by the hyposulphite of soda. A portion of the contents of a kettle of boiling water poured over such a print will apprise the photographer of his error, as it will immediately stain the print a dirty yellow, owing to the formation of silver sulphide.

AT the last meeting of the Photographic Society of Great Britain a print was exhibited with a number of white spots upon it, which had made their appearance within a few weeks of its production. The question was raised as to the cause. Various suggestions were made as to their origin, but they were all more or less inconclusive. This character of spot has been very prevalent during the past two or three years—far more so than we ever remember before. The particular kind of spot referred to is a small white one, though it may sometimes have a very slight yellow tint. It is quite distinct from the small yellow ones often produced by sulphuration. The edges also are more sharply defined. Some prints may only have one or two spots, while others in the same batch may have a dozen or more; and they are not seen while in the toning or the fixing bath. It is not until they are finished, or more generally a few weeks afterwards, that they make their appearance. A close examination with a magnifier shows that some of the spots have a nucleus, while others on the same print have not. Yet the trouble evidently has one common origin.

IF the spots in question were due to the paper, one would expect the effect would be seen before the picture is finished. If they were due

to anything in the manipulation—for example, while they are in either of the solutions or in the washing waters—it might well be imagined that they would not be so sharply defined at the edges, but more diffused, like those arising from sulphuration. It would rather appear that the injury has its origin after the print is finished, so far as the manipulations are concerned. Mr. W. Bedford mentioned that he had known dust from burning coke to produce similar spots. Every example of this particular spot which has been brought under our notice has been perfectly consistent with its proceeding from some such cause as this—that is, from particles of deleterious matter coming into contact with the picture while in a moist or semi-moist condition. It is easy to see that anything like dust from a coke stove falling on a damp print would be productive of injury.

THERE are many matters which at times are disseminated through the atmosphere of photographic workrooms—hyposulphite of soda, sulphate of iron, pyrogallie acid, bichloride of mercury, &c., for example, all of which might act injuriously on a moist photograph if they settled upon it. When a solution of these substances is spilt upon the floor, and dry, small crystals form as a matter of course. The finer of these become diffused through the air as dust, whenever the floor is swept, and ultimately subside again to be redisturbed on some future occasion. Now it is very manifest that if a batch of prints be drying, either before or after mounting, and any particles of the materials just alluded to, or many others to be met with in photographic workrooms, come in contact with them they will act the reverse of beneficial. The effect even of a very minute particle of the bichloride of mercury, for instance, would be especially baneful.

IF any evidence were necessary of the rapid spread of amateur photography it was certainly to be found at the Universities boat-race last Saturday. Cameras were to be seen here, there, and everywhere. "Detectives" were, undoubtedly, in the ascendant. The light at the time was not, perhaps, all that could be wished, but still some hundreds of negatives were taken. We have been shown some very successful detective shots of different groups of people surrounding those itinerant vendors of purses containing coin, and the gentlemen who perform "the three card trick." These were all very truthful, and characteristic pictures of the motley groups to be met with on the boat-race day.

WATER-COLOUR artists are always particularly careful with regard to the glass used in glazing their pictures, that it should be as free as possible from colour. This is a point upon which photographers bestow but little attention, even with their coloured work, beyond that the glass is tolerably free from air bubbles. It is manifest that if any tinted medium is placed in front of a picture, the colour of the latter, as well as that of the mount, must be to an extent modified. Now much of the glass at present used for picture frames has a pronounced green tinge, which, it is scarcely necessary to say, is highly objectionable. The influence of bad glass on a photograph was well exemplified in a picture we noticed at the Crystal Palace the other day. The glass had been broken and a portion had fallen out of the frame, leaving a part of the picture bare. That portion appeared of a different tone from the other, and was far more brilliant, while the tint of the mount was also different. In fact, the picture and its mount would have shown to far better advantage had it not been glazed at all, or at least with such glass as had been used.

In glazing show-cases, when plate glass is employed, care should be taken that it is as free as possible from colour. Some kinds of plate glass have a strong green tint, while others quickly acquire a yellowish brown tinge by exposure to light. Both these varieties should be avoided for photographic show-cases, as they materially degrade the brilliancy of the pictures.

ALTHOUGH the cold tones of platinum are now so much in public favour the taste in this direction does not seem to extend to lantern pictures when they are projected on the screen. Here cold tones do not seem to be so well appreciated, and why this should be it is difficult to conceive. In a lantern exhibition pictures of a cold tone, however good

they may be, seldom meet with the same approbation as those that are of a warmer colour. If an opinion may be formed from the applause with which a rich brown toned slide is usually greeted, that colour would seem to be the one most in favour with the public, so far as lantern slides are concerned.

BROWN tones were always most admired in the old stereoscopic transparencies, although purple and purple blacks were most sought for in paper pictures. By the way, we have recently seen some excellent stereoscopic slides on opal glass which could be viewed either by reflected or transmitted light. They were on glass thinner than that generally used for ordinary opal pictures, and it was well adapted to its purpose. With glass of the ordinary thickness these particular pictures would have looked too heavy when seen by transmitted light. If a demand for a thin opal glass, or one containing less opaque matter, were created it could easily be supplied. Stereoscopic portraits on "porcelain" are very effective, and might become very popular if introduced commercially.

IN the project of the Lord Mayor for enabling certain British craftsmen to visit the forthcoming exhibition in Paris, photographers and photo-mechanical workers have not been forgotten. This is very satisfactory, and those who go, especially the latter, can scarcely fail to profit by their visit.

DURING the discussion following Mr. Andrew Pringle's paper on *Photo-micrography*, at the Camera Club Conference, one of the speakers strongly advocated photogravure for illustrating pathological works, as a means for obtaining permanency coupled with accuracy. It was mentioned that many illustrations, though most carefully drawn, often conveyed a very different impression to the mind of the student from what a photograph would do, or would the object itself seen under the microscope. Photography has been extensively employed in connexion with pathology, but, unfortunately, many of the illustrations were printed in silver, and have now faded to such an extent as to be nearly as misleading as some of the hand-drawn ones. In future, there is little doubt but that one or other of the photo-mechanical processes will be employed for all such work.

MR. VALENTINE BLANCHARD on Tuesday last gave an exhibition, at Anderton's Hotel, of specimens by his new method of producing photographs in platinum black. The paper is printed in the ordinary way, and can be watched from time to time as the printing proceeds. Toning in a salt of platinum, and fixing in hyposulphite of soda follow, the result is a print which cannot be distinguished from one of those platinotypes with which the public are now so familiar. We shall probably have more to say concerning this process soon.

Our Portrait Gallery.

I.—FREDERICK YORK.

WE commence this series with the portrait of one whose name is well known all over the world, more especially in those parts of the world where photographic lantern slides have penetrated.

Mr. Frederick York has entered upon his jubilee year, it being just fifty years since he was apprenticed to a chemist. The subject of our sketch was born at Bridgwater in 1823. Intended for the law, a few months in the office convinced him that he had no vocation for the profession, and so the articles were not signed. He was apprenticed in 1839 to a chemist at Bristol. Hence this year, as above stated, is his jubilee of commercial life. At that time Fox Talbot's discovery attracted general notice, and Mr. West, of the Observatory at Clifton, made photogenic paper, and sold it to chemists to retail at one shilling a packet. It was used principally for printing fern leaves, lace, &c. This was his first introduction to photography.

In the winter of 1853, when residing at Bath, he had severe hemorrhage from the lungs, which confined him to the house for four months. The doctor advised his going to a warm climate, and he decided on going to the Cape of Good Hope, which he did the following year. He called on a friend, Mr. Cogan of Bath, to have his portrait taken, and having told him of his plans, he suggested his going in for photography, and kindly offered him every assistance

and the use of his studio. Although Daguerreotype was then the recognised process, his friend was working collodion—in fact, was one of the pioneers of that process.

On his arrival at the Cape, in January, 1855, he found there was an opening, and he decided on abandoning physic for photography. The things he took out were soon used up and could not be replaced for five months, as there were no steamers running to the Cape at that time, and collodion there was unknown. Iodide or bromide of ammonium could not be obtained. The Dutch ether turned blood-red when iodides were added, and the spirit of wine was so carelessly distilled that it was almost useless. He had to redistil both ether and spirit, to make gun-cotton and the iodides and bromides of ammonium; and nitrate of silver he made out of Mexican dollars. Contrast all this with the facilities of the present day! He mastered it all and may be considered the first who introduced the collodion process into South Africa. He became a large importer of photographic material, and taught photography to many who travelled through the country. The change of climate was most beneficial to his health, and he never had a return of the old complaint. He returned to England in 1861, and after twelve months' rest started on outdoor work. He took over one thousand views of London in four sizes. His stereoscopic, cabinet, and large sizes (8 × 6 and 12 × 10) of animals at the Zoological Gardens, taken by the collodion process, have not been excelled.

Having little to do in the winter, he turned his attention to making lantern slides, which has grown into a business, requiring fifteen thousand negatives. His printing works are at Bridgwater, his native town, and his warehouse at 87, Lancaster-road, Nottingham, London.

Mr. York used to be an active member of the various Photographic Societies. He was a member of the Council of the Parent Society, Vice-President of the South London, and Trustee to the Photographic Club. Increasing deafness has induced him to retire.

Mr. York is a man of a mild and genial disposition, and possesses a vast fund of photographic knowledge, which he has ever been ready to place at the disposal of his brethren in the art.

The portrait is engraved from a photograph by Mr. Abel Lewis.

A METHOD OF RAPIDLY ELIMINATING HYPO FROM SILVER PRINTS, AND OTHER NOTES ON SILVER PRINTING.

THE thorough elimination of hypo from silver prints is a thing that has always been a troublesome matter in connexion with the common printing method, and, even if it be granted that insufficient washing is not so entirely to blame for the want of permanency of prints on albumenised paper as has sometimes been thought, any method of facilitating the operation of getting rid of the objectionable salt will be welcomed by photographers. "Hypo-eliminators" seem to be looked upon with more or less suspicion, rightly or wrongly I will not venture to say. Against washing machines I have nothing to say, but they are generally somewhat expensive, and often cumbersome,

especially for large prints. I have found the following method of hand washing thoroughly efficient for moderate batches of prints, say two or three dozen 12 × 10 prints, or double as many cabinets. For large numbers the process would be tedious. For such numbers as I mention, the whole thing may be done in half an hour.

The prints are fixed as usual, but, instead of removing them from the dish of hypo, the hypo is poured off and the mass of prints is drained till the solution only drops from it. The dish is then filled up with warm water, and the prints are, one at a time, removed by hand from it to a second dish full of cold water; the cold water is poured off and is replaced by warm water; they are then removed to a third dish of cold water, this is poured off, warm water is added, the

prints go back to the second dish, again filled with cold water, the cold water is drained off, and warm water is added for the third and last time. The prints are now removed one at a time to a large tub full of cold water. They will float for about five minutes on the surface of this, but at about the end of that time the prints will sink singly and very slowly to the bottom of the tub. By the time that the last has sunk the prints may be taken out of the tub and dried. The most delicate test will fail to detect any trace of hypo in them.

Advantage is taken throughout this method, by the alternate use of hot and cold water, of getting rid of the hypo by virtue of the tendency to diffusion that there is between miscible fluids of different temperatures. As to the heat of the "warm" water to be used, so far as the efficiency of the elimination is concerned, the hotter it is the better. Water even nearly boiling does no harm to silver prints on either plain or albumenised paper, but, besides the natural difficulty of handling prints in very hot water, it will be found that the paper is rendered so soft that it is almost impossible to avoid tearing the paper, especially in the case of large prints. I have not taken the exact temperature of the water that I use, but I imagine that it is between 100° and 120° Fahr.

I have printed in another place a method of reducing prints on albumenised paper from the crumpled-up form that they assume on drying to a handleable form, but probably few of my present readers have seen the little book in which the method is given. I may therefore, perhaps, be forgiven for repeating it here. As to the plan of drawing the print under the blunt edge of a paper knife, I know that it works well enough in the hands of some, but I equally well know that it will not work in my own hands at all, except in the case of very small prints, and that there are many who have quite as much difficulty with the method as I have. As a rule, if I attempt to flatten prints in this way, I tear a most unconscionably large percentage of them, and do not get the rest flat after all.

Here is the plan that I recommend:—The prints on coming from the washing water are blotted off with blotting paper, and are laid face downwards on a clean cloth, or on any clean surface to which there is no danger that they will stick. A wooden roller about an inch thick and three or four inches longer than the width of the prints is needed. When the prints are all but dry, one is taken and is wrapped tightly round the roller with the albumenised side outwards, the end of the next print is caught for half an inch or so under that of the first, and so on, the roll being twisted up as tightly as possible after

each print has been added. At the end a piece of common paper is caught in by the end of the last print, it is rolled round the whole, and is secured by a little gum. The roll is laid by for a day or longer, and at the end of that time may be opened, when it will be found that the prints have a fine surface, and no longer show that irritating tendency to curl towards the albumenised side that they did at first.

Last, a hint communicated to me by Mr. F. W. Strange, which will, I think, be found of use to those who produce enamel prints, either by the use of the gelatine-citro-chloride paper now so popular, or on ordinary albumenised paper by the aid of gelatine or collodion, or both. All those who have produced such prints know that one of the greatest troubles is to mount them without spoiling the surface. It is necessary to attach the mount itself, or at least a tolerably thick piece of cardboard, to the back of the print, whilst this latter is still attached to the glass that is used to give the enamel glaze. In either case there is some trouble. If the cardboard is thick, the time taken for drying is excessive, and, moreover, the print is apt to be torn from the glass when it is still only half dry by the warping of the board, in which case it is ruined. If the cardboard is too thin, the water of the mountant used to attach it afterwards to a thicker board is liable to penetrate and destroy the glaze. There is a common quality of paper that is purchasable from all stationers; it is thin, and has one side covered with a black, glazed pigment that is quite insoluble in water. This paper is just so nearly impervious to water that if it is pasted on the back of a print drying on glass it will not prevent the drying, but will permit of the print being afterwards mounted with an ordinary mountant, without sufficient water penetrating to damage the glazed surface. The prints mounted on the glass, and ready for stripping when dry, are allowed to get nearly dry, a piece of the glazed paper of the size of the print is affixed to the back with any mountant in which water is the solvent, the white and unglazed side of the paper being, by preference, pasted to the print. The drying of the print is very little impeded, it will strip just as if no paper were attached to it, and it may afterwards be mounted in the ordinary way with thick glue. There is, of course, no advantage in the black colour of the glazed surface of the paper that intervenes between the print and the mount, but there is certainly no disadvantage in it, and I do not remember to have seen paper of the kind that I refer to of any colour but black.

W. K. BURTON.

CRYSTAL PALACE INTERNATIONAL PHOTOGRAPHIC EXHIBITION.—III.

THE prizes awarded in the art department of this Exhibition have now been published. They are as follows:—

Gold Medal for Best Alcove.—E. Davey Lavender, Bromley.

Silver Medals.—F. de P. Cembrano, London; W. W. Winter, Derby; H. P. Robinson, Tunbridge Wells; Miss F. A. Harvey.

Bronze Medals.—Class A (Outdoor Photography): Green Brothers, Grasmere; F. M. Sutcliffe, Whitby; H. W. Gridley, New York; Richard Keene, Derby; Harry Symonds, Portsmouth; Lyddell Sawyer, Newcastle-on-Tyne.—Class B (Indoor Photography): W. J. Byrne, Richmond; W. Tavener, jun., Stamford-hill, N.; G. W. Wilson & Co., Aberdeen; Webster Brothers.—Class C (General): F. B. B. Wellington; F. H. Evans, Stamford-hill, N.; F. W. Edwards, Peckham, S.E.; J. G. Tunny, Edinburgh; Photophone Company, Old Kent-road, S.E.

Special Medals—Bronze.—Gambier Bolton (Animal Studies); The London Stereoscopic and Photographic Company, Limited (General Excellence); Thomas Julius Hurst, Muddersfield (Platinotypes); The Eastman Dry Plate and Film Company, Oxford-street; Morgan & Kidd, Richmond; R. Faulkner, Baker-street, London; G. Gillard, Glasgow; F. W. Hart, London.

Messrs. Sands & Hunter exhibit one of their 10×8 Exhibition cameras, a new light Imperial camera that has a long range, a variety of London street views taken by Mr. William Cobb, in which there is considerable depth of definition, stated to be largely due to their shutter of the form which commences its exposure at the centre of the lens, and to which has been added several improvements. A magnesium lamp is also exhibited, the peculiarity in which is that the magnesium powder is projected upwards through the flame, any unconsumed particles being caught by a plate a little distance above and prevented from being lost.

Messrs. George Houghton & Son have Hart's flash light erected upon a stand. They exhibit the Eclipse camera, which is fitted with Wray's new shutter; lenses, portable dark rooms, sinks, print washers, and studio accessories are included among the many things which this firm exhibits.

The Photographic Apparatus and Chemical Company show some very elegant things, amongst them being a convenient folding lamp for the dark room, shutters, and Victoria developers. They also have a fine exhibit of general photographic apparatus.

Among the exhibits on the stand of Walter Lawley is a form of iris diaphragm which has been fitted with a convenient spring stop on the outside. A very compact "Clipper Tourist's Set" is also shown by them. This set is packed in a suitable case, which also contains the stand for the camera, the space occupied by the

Fig. 8.

whole outfit being 18 × 10½ × 3½ inches. One of his cameras—"The Improved Long Focus"—is fitted with a rack to the swinging back. He also exhibits a convenient form of head-rest, in which the rests are tightened by means of a thumbscrew at the back.

One of William Ford Stanley's specialities is in the manufacture of cameras by machinery, the component parts of which are formed of small sections of wood braced together with wood, metal binding being avoided, he having found that they are better enabled to stand hot climates. A new form of magnesium lamp for enlarging is also shown. The magnesium ribbon is wound upon a reel at the

Fig. 9.

back, and fed into the interior of the lantern by means of a handle. In front of the lamp is placed a sheet of glass. A small shade protects the flame of the magnesium. The sides of the box, which is of a pyramidal form, are painted white on the inside and radiate the light equally upon the negative.

Ferrers's new patent film carrier is also shown. This is capable of carrying and changing fifty films in the space of two double dark slides. It is intended to modify this carrier to enable plates also to be used.

This firm also exhibits a convenient form of developing table furnished with a rocker for the developing tray. The light is so arranged that it is reflected up through the negative whilst it is being developed. This table is furnished with curtains which when closed form a compact dark room.

A large number of designs of mouldings are exhibited by Messrs. J. Eede, Butt, & Sons, such as undercut mouldings, frames formed of a combination of running and carved mouldings, and also of a combination of woods such as oak and walnut and mahogany, &c.

The space occupied by the exhibits of Robt. Abrahams is considerable. Not only does this firm show a great variety of apparatus, but have men working at gold-stamping, litho-printing, gold-edging, and other processes pertaining to photography. Their special form of detective camera is depicted in the cut on the following page.

The plates are placed in carriers and occupy the lower chamber.

After exposure they are, by means of a lever from the outside, transferred to a chamber above. The external appearance of this detective

Fig. 10.

camera resembles that of a leather dressing case. This firm has a varied exhibit of the different apparatus used in photography, consisting of tents, camera stands, shutters, frames, racks, cameras, lanterns, &c.

F. W. Hart has a number of flash-light lamps on exhibition, several being operated at once by means of a central reservoir of compressed air. Several fine photographs taken at night adorn the stand occupied by Mr. Hart.

The "American Brand" Manufacturing Company have a number of rockers on exhibition, the principal one being for a developing dish, with a clockwork motor. By this means negatives that are slow in development may be left for any length of time, the motor causing the developer to flow and reflow over the plate. It will be remembered that an apparatus of a similar character was exhibited by Mr. S. D. McKellen at the Derby Convention. We mention this because it is stated that a patent has been applied for in the interests of the American invention.

Rooke's simplex automatic print washer is exhibited by its inventor, Mr. W. Rooke. The working of it may be described in this way:—A tube is placed across the centre of a circular bath, to which is attached an indiarubber tube from a tap. Small holes are drilled in

Fig. 11.

the tube at an angle to emit the water, and thus cause it to flow round, keeping the prints always moving. The amount of water from the inflow is less than the outflow, so that the syphon draws off about two-thirds of the water, when it is stopped by the air check. It fills again, and so the action goes on, taking five or six minutes for each change of water. By this means the water is rendered weaker of contamination at each change. About six changes of water is considered enough for one batch of prints. The bottom is conical, thus preventing the prints from dragging.

E. G. Platt has a small exhibit which he terms the "Amateur's Friend." This case consists of brass fittings, bellows, and other parts for cameras.

Among the exhibits in the stand of J. Mothersill we observe, *inter alia*, extremely low-priced photographic outfits, doubtless intended as an inducement for the tyro to have something better after he fleshes his sword.

J. H. Skinner & Co. are also exhibitors of low-priced outfits, intended for those whose purses are not plethoric.

Spicer Brothers exhibit cameras, tripods, and studio stands, a variety of lenses and backgrounds, and specimen photographs taken on their ready-sensitised paper.

J. Theobald & Co. have a considerable exhibit of lantern slides printed on paper for transferring to glass; they also show a portable electric light of 2½ c. p.

A. M. Zimmermann exhibits Schering's pyrogallie acid, collodion, iodide and bromide salts, neutral oxalate, and other chemicals, also albumenised and sensitised paper.

James Wood (Liverpool) exhibits his washer and adjustable rack for plates, of which a notice appeared in this JOURNAL a few weeks ago.

DISSOLVER FOR A SINGLE LANTERN.

DURING the past season I have used with great satisfaction, both with oil and limelight, a small square of ground glass that is mounted in a brass frame and fixed on the end of the object glass of the lantern, by means of a fall back rim and set screw. It gives just the appearance of the rolling curtain effect, and enables one to see at a glance if the slide is inserted the right way, and gives sufficient time to rectify any mistake that may occur without the audience being aware of it.

A drawing and full description may be seen in THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC, page 136, for the year 1885, by Mr. Antony Philbourne. It is a real good thing, and I trust that you will kindly insert this in justice to the gentleman who, I believe, first published this useful invention.

THOMAS GULLIVER.

CAMERA CLUB CONFERENCE PAPERS.

I.

We now give the first of the series of papers read at the Conference of the Camera Club last week, and shall continue them till finished, not preserving, however, their sequence in the order read.

THE RELATION OF PHOTOGRAPHY TO THE PICTORIAL ART.

By JOHN BRETT, A.R.A.

LET us first consider what are the pretensions of the painter's art, and what it sets out to do; then let us examine those of photography, so as to determine what capacity it has to become its rival; and, lastly, let us find out how far either of these two arts are or can be serviceable to the other. Both may be in a sense called pictorial, for they both set out with the same fundamental purpose, and at first their paths appear to lie parallel.

The basis of all good pictorial art consists of a reproduction of natural images or views, and the photographic art, no less than that of painting, aspires to get a true and honest representation of real things, and especially of transient appearances; but when the theory of the subject is examined the parallelism of their paths is soon found to cease, and farther on they diverge widely, never to meet again. It will be my endeavour to show the extent of their parallelism and the necessity of their divergence, and if the result of the inquiry should tend to curtail the aspirations of the photographer I shall regret that result; but we want, above all things, to get at a sound theory, and to set forth the plain, unvarnished truth. Assuming, as I do, that the painter's art is founded on correct representation of real things, it is obvious that the photographer starts with an advantage, but this advantage is limited to facts of form.

In respect of rapidity, also, he has the advantage; but the elasticity of the painter's art, on the other hand, gives him a clear lead, inasmuch as he can manipulate his image at pleasure, so as to produce on the spectator any desired effect. Here it is that the paths begin to diverge. One of the functions of the painter's art is to exalt natural appearances, but the misfortune of the camera is that it is liable to degrade them. We must be careful here to note that exaltation does not imply misrepresentation, and, the distinction being rather subtle, I must dwell upon this for a few minutes to explain the difference. Let us consider how it is possible to exalt natural images.

Taking an abstract point of view, is it not presumable that they are already sufficiently beautiful, and that any tampering with them is irreverent and injurious? In a few rare instances this is doubtless true, but, on the other hand, if we consider Nature from man's point of view, nearly all her performances have flaws and blemishes, and exhibit such blundering as cannot be overlooked.

The philosopher, of course, values what we call Nature's defects, and accepts the whole turn-out as the best of all possible worlds; but Art has to address herself to mankind as it exists, and allowance has to be made for preconceptions, both inherited and acquired. Art is not intended for gods, but men. The painter's art proposes so to set forth natural images as to develop their utmost capacity for charming mankind, and it proceeds on the assumption that the pleasure afforded by beauty is one that does not blunt our sensibilities, but improves and quickens them, and tends to disqualify them for unworthy entertainment; that beauty, in short, is an unalloyed good.

It is true that the photographer has some power to improve natural images by touching out or reducing their defects, but unfortunately he has not an equal facility for accentuating the beauties; and so it usually happens that whilst he is busily engaged in touching out the defects of the picture, he is in an equal degree depriving it of character and reducing it to insipidity. Artistic work is always to a great extent done from memory, often entirely so. Most of the choice and exquisite appearances of nature show themselves but rarely, and too often refuse to sit for their portraits. Even amongst the faces of our fellow-creatures we know that their gleams of consummate beauty are only revealed under peculiar circumstances, and these circumstances can very rarely, if ever, be available to the photographer; but the artistic memory can treasure them up and reproduce them, even after intervals of years, like the phonograph

does with sounds. Memory, therefore, is one of the chief of the artistic equipments. All the work done from memory is liable to be biased by the personal taste of the performer, also by his intellectual calibre, and by his experience of the range of natural variations; and when his admiration for his model is raised to the pitch of enthusiasm he unconsciously emphasises those elements of the scene which especially interest him. This is the reason why artistic representations often surpass in delightfulness the real images.

One of the strongest resources of the pictorial art is composition. Composition means such an arrangement of several images that they shall add lustre to one another. Composition depends partly on contrast—contrast of shape, or of mass, or of texture. I do not mention colour for obvious reasons. In some degree the photographer can compete with the painter in composition, though in this he is heavily handicapped, because he has to take the items of his picture as he finds them, whereas the painter can adapt them to his purposes by boldly altering them, although it should not be overlooked that he is limited in doing this by the necessity of keeping within the laws of nature and of congruity. Contrast is only one of the elements of composition. An equally important element is the arrangement of the lines, quantities, and intensities of the masses in a harmonious series, the purpose of which is to bind together in artistic unity a sequence of impressions, so that they may all be appreciated simultaneously in the completed picture. In a fine composition nothing could be omitted without compromising all the rest, just as in a closely reasoned argument the omission of even one word is enough to throw the whole train off the rails. This problem of composition in pictures is necessarily abstruse, and fine examples are only achieved intuitively by specially gifted persons.

There is another resource of the pictorial art available also to the photographer, though only to a limited extent, and that is sentiment. Let us examine this quality to see what it depends upon, and what is its value. Views of the external world produce upon intelligent spectators a large variety of impressions, some of which are sublime, and worthy of perpetuation (these are comparatively rare); others of them are indifferent or commonplace, and constitute a large majority; whilst some others are gloomy and distressing. Poets, romancers, and painters have found by experience that in one respect there is a strong family likeness amongst their audience. They are all most deeply moved by beautiful and sublime images, which are more or less adulterated or tinged by the gloomy and the distressing, the effect of which is to connect them with human experience. It is evident that this experience has for so many ages been developing under the shadow of adversity and conflict, that the tone of its inherited sentiment is dimmed with half tint; and so universal and persistent is this tone that I suppose no healthy nature ever completely shakes it off. When men have honestly and boldly lived out their little lives, the closing in of their day is symbolised by a sunset, the beauty of which depends on some bars of dark cloud. The strong and successful man, when surveying the retrospect, says, "I have fought a good fight;" but when Tennyson had to describe the insipid young lady, whom he called a "milk-white fawn," he disparagingly remarks that she had but "fed on the roses and lain in the lilies of life," thus pointing emphatically to the unartistic tendency of an unclouded experience. This I take to be the explanation of the undoubted fact that merely accurate representations of beautiful scenes flat upon experienced people, and fail to move them to enthusiasm.

The whole race of photographers doubtless exert themselves habitually to produce beautiful pictures, and when the best of their efforts are sifted out to form the annual exhibition the show is of very great interest on technical grounds; but it will not be denied that it wearies rather than enchants the non-professional spectators, and that few, if any, indelible impressions are carried away in their memories to form the subject of delightful reflection. Thus, I think we must admit that the direct artistic uses of photography are limited, and have none of that commanding influence over men's minds which is characteristic of the fine arts. Nevertheless, Photography is an invaluable servant, and, I may add, an invaluable teacher to the artist, and I shall presently show the nature of her lessons. The production of a painted picture is so much under the artist's control that he can have it turn out how he likes, if only he has a clear conception of how it ought to look when done, so that the operation is entirely delightful to him from beginning to end.

You may occasionally produce an artistic picture in photography; but so many circumstances have to conspire together to ensure such a result that successes are extremely rare, and they go to show that the photographer himself is a miracle of perseverance and cheerfulness. Any moderately gifted man embarking in such an enterprise should be warned against a lunatic asylum or an early grave. His hair must soon become white, for nothing wears away a man's vitals like repeated failure. It is obvious that in respect of form the camera can give far more accurate representations than the painter can pretend to; but it is disheartening to know that the taste for accuracy is not a plentiful endowment of human nature. People are rarely thankful for it, generally indifferent to it, and in some cases they are offended at and resent it. This leads us to consider the importance of photography as an educator—first, of the photographer, then of the painter, and, lastly, of the public.

Before a photograph can be taken, the operator has to observe his model attentively—and observation, I submit, is the major part of education. It is only after long training that the observing faculty becomes

so keen and active that a good photograph can be confidently expected. Most operators never outlive the fluking stage. The cultivation of this faculty is no simple matter; it involves a taste for analysis. Any observation that is not analytical is vague and useless. You have to consider your subject, first, as a group of masses of light and dark; then you think of the arrangement of line caused by the coincidence of the boundaries of these masses; then you have to study the distribution of the accent or emphasis in both elements; and until you have become in this way a trained analyst all your endeavours will be empirical, or shots in the dark.

Even if the photographer was at the outset a highly cultivated person, it is certain that his practice with the camera will inevitably improve him, whatever his natural calibre may be. It will compel him to learn composition and chiaroscuro with the utmost despatch. He will pose a group, say, a dozen times in a morning, and when in the afternoon he finds that each arrangement is more hideous than the others, and that his box of plates has been wasted, he begins to feel that he must take pains, and thus the most valuable part of education is developed.

In the practice of the painter's art you can deliberate and make alterations, so that the intolerable sense of disappointment is evaded, and you can be as idle as you choose at small expense.

Now let us consider photography as an educator of artists. Its direct use in this respect is much more limited than would be supposed; first, because of the great difficulty of copying a photograph on account of its small scale. All students of drawing are aware how much easier it is to reduce than to enlarge the scale of their model. The image in ordinary photographs being smaller than the real object, its intricacies are much more perplexing, and its details more difficult to follow, and the errors in the copy are amplified. When the natural object is inaccessible to the draughtsman, of course he is glad enough of the photograph, but the instances are rare in which its value is continuous, since artists seldom require the same model more than once. By the time that the student has become a skilled draughtsman he has had a large experience, and his memory has become so stored with images that it may be considered as a complete dictionary of natural phenomena, and the immense practice that has to be gone through in acquiring this knowledge develops such rapidity of execution that it is seldom worth his while to put up with a photograph as a model, still less to go to the trouble of enlarging one. In fact, when the real object is accessible he could do the drawing direct in less time than he would have to expend in taking and developing the negative, not to speak of printing.

The most frequent instances in which photographs have been copied by painters occur in the practice of portraiture, where the sitter's type is precious. Then it is sometimes of vital importance; but I am sorry to testify that most portrait photographs are so misleading, and so much uglier than the originals, that the trouble of the painter is immensely increased by their use. It is also obvious that one photograph can only exhibit one phase of the sitter's character, and far more than this is required in a successful portrait. The chief direct use of the camera to the artist lies in its power of securing images of rapidly moving animals. I think that painters owe a great debt of gratitude to Mr. Muybridge for his photographic investigation of this subject, and the splendid demonstrations he has given of the footfall of galloping, trotting, and walking horses; and we ought also to offer our hearty thanks to the University of Pennsylvania which has so handsomely forwarded his work.

In landscape, the misfortune of the camera is that it degrades the really fine scenes by expanding the scale of the foregrounds in relation to the other planes of the picture, where the more important features can be advantageously seen, so that the areas of the latter are dwarfed. Mountains, in fact, are made into molehills, and the photographer is driven to the device of cutting down his print so as to show nothing but the molehills. Landscape photography at present also suffers much from the fact that the horizontal rays are less actinic than the vertical ones. The clouds which generally govern the sentiment of a landscape are fatally affected by this misfortune, because all those that present beautiful forms and are valuable elements in a composition occur near the horizon, where the disadvantage is most apparent. The zenith clouds can be photographed very well, but unfortunately they are of no pictorial value.

Perhaps the chief practical use of photography in the painter's studio lies in its aptitude for the reproduction of drawings. My own collection of photographs from drawings, by Michael Angelo, Leonardo, Holbein, and others, contains examples that represent the masters nearly as well as the originals. These prints cost only a few shillings, whereas no sum could be mentioned that would purchase the originals. The educating influence of photography upon the average public is rather too large a subject to deal with in this paper, though it is certain that that influence is favourable to the fine arts. I think its first effect is to disenchant them with the world in which they live and move and have their being; but it is probable that in a wide sense the multitude of scenes presented to the desultory spectator are calculated to awaken in his progeny an interest in the visible world which might otherwise have remained latent. I think there is an off chance of this coming to pass by heredity. "Know thyself!" is a precept that is often effectually driven home by the raw photograph, whilst the cooked one affords still deeper lessons. The touching of portrait negatives by the trade I regard as an acute instance of moral depravity. It is either a poor unworthy attempt to disguise bad

work, or else it shows a deliberate purpose to demoralise sitters and filch their cash by a prostitution of the noble art of photography.

One more paragraph will now conclude my paper. I have only to point out what constitutes the high importance of the painter's art. It is the display of consummate handicraft. The French call it *tour de force*, but it means essentially a tribute of admiration on the part of the artist. To the spectator the enchantment of masterly manipulation is irresistible. Hardly any painter of modern times has exercised so great a charm over mankind as Rembrandt, and that charm is by no means dependent on the exaltation of the images, but chiefly upon his marvellous command of them, or his supreme manipulative skill. The same remark might be applied, though in less degree, to Landseer. We set out in this inquiry from an identical purpose. We saw where the paths of the two arts began to diverge. We have now arrived at a situation where photography and fine art are no longer in the same field of view—one being the handicraft of men, and the other an operation of chemistry more or less directed by taste.

LENSES—PHOTOGRAPHIC AND MICROSCOPIC.

THE scope of our inquiry to-night is restricted within matter-of-fact bounds by the limiting title of the paper, or I might have been tempted to speculate upon the discovery of the power of transparent sphere-like bodies to magnify objects. Solomon's oft-quoted saying, "There is nothing new under the sun," must apply in this case; and though the history of lenses and lens making is of comparatively modern date, and excursions into the domains of tradition rather the prerogative of the poet than within the province of a man of science, they cannot be altogether inappropriate to the amateur. Profit may accrue, and the pleasures of the imagination count for something. It is not wise to despise the bookworm or antiquarian, and even in this ultra-materialistic age our self-sufficiency is not armour enough if we do so. The man who speculates as to the future, and endeavours to penetrate into that vast and mysterious eternity which lies before us all, is applauded for his daring; if glancing but a few years ahead he predict some coming change or invention, his forethought is marvelled at, and he can remain quiet for the rest of his life convinced that he has proved himself a "dressed clever fellow." It is too often overlooked that behind us, as before us, is an eternity—a veritable ocean whose shore is the present day, whose surface is troubled by the winds of time, and whose ships are men. Our antiquarians and bookworms are the lifeboat and salvage men, whose labours are to save for present and future generations the reputations of great men and the wreckage of their works. Some of these salvage men are practical people, others, day dreamers, and again others unite both capacities. I believe I belong to the class of idle day dreamers, and would rather indulge my fancies in the present instance in speculations as to whether some lozenge-eyed Chinese or dusty Brahmin first became aware of the properties of lenses, and by what happy chance so important a discovery was made, than trouble about dry, scientific affairs. Many of you have no doubt read the story of "The first lucifer match," in which it is recounted how a packman travelling in the Highlands called at a cottage, and after an adroit speech suddenly struck a lucifer match, and almost drove the good country folk out of their wits with terror and amazement. This might serve as an illustration, though I fancy that the discovery of the power of magnifying glasses must have been attended with something of the delight and astonishment attributed to the savage, who for the first time becomes acquainted with a mirror, a glass bead, or a top hat. It is time to remember that this is a paper upon lenses—photographic and microscopic; but when I contemplate the scientific Sahara into which I am going to lead you and reflect that this is a total establishment, my conscience prickles a little, and a vision of the members disappearing in twos to see a friend rises up before my eyes.

A little reflection has convinced me that the title of this paper is scarcely in order, for although it is intended for the members of a photographic association, microscopic lenses have the first claim to our consideration, both from historical and scientific points of view. Still earlier, I believe, comes the telescope, which, like the microscope, unites with the camera in the work of photography, and also claims consideration from us this evening. The selection of lenses as the subject of a paper is due to our worthy Vice-President, Mr. J. P. Gibson, and as at the present moment the interest in lenses has received a great impetus by the introduction of new forms of glass and improved constructions, perhaps no better subject can be chosen.

Within the last few weeks a number of valuable articles have been contributed to the photographic journals, and these without a doubt the most of you will have seen. They have more than covered the ground I should traverse, and perhaps the best thing to be done after dealing with microscopic lenses is to draw attention to some of the salient points in these articles and add a few of the mental memoranda that I have made at various times.

The double convex magnifying glass was probably known both to the Greeks and the Romans, and five centuries B.C. a "burning sphere" was spoken of by Aristophanes. Zacharias Jansen is stated to have manufactured microscopes previous to 1590, the date when the telescope is supposed to have come into existence. As with other important inven-

tions, various persons are credited with being the real original inventors, and John Baptista Porta, Jansen, and Galileo divide the honours of the telescope, whilst for the microscope Drebell (1621), Fontana, and Jansen compete for priority. Fontana did not make any microscopes previous to 1618.

Microscopes are of two descriptions, simple and compound, and either of these may be achromatic or non-achromatic, but the non-achromatic compound microscope has been relegated to the repository of toys. Such ignominy has not fallen to the lot of the non-achromatic simple microscope, and for dissecting purposes it still retains its position as a scientific instrument. I have here a microscope made about 1742, and described by Mr. Henry Baker, F.R.S., in his treatise published in that year, as a new invention. It is a pocket microscope with a speculum, and an engraving of it, as mounted upon a handsome scroll stand, graces the title-page of Hogg's admirable work on the microscope. I had the top of the original scroll, but it was intrusted to a friend who kindly undertook to make me a stand after the model of the original. Must I add that the top of the scroll has been lost and the stand is still unmade. This microscope is furnished with a complete set of beautiful lenses of the following foci, $\frac{1}{2}$, $\frac{2}{3}$, $\frac{4}{5}$, $1\frac{1}{2}$, $2\frac{1}{2}$, 4 , 6 . Of the seven, five are original, and two, the $\frac{2}{3}$ and $1\frac{1}{2}$ -inch lenses, are additions, and these two, it will be noted, are furnished with Lieberkuhn's, an invention which came into use in 1710. Two years previous to this, Lieberkuhn invented the solar microscope, and if you examine my instrument you will observe that it is arranged to be used as such. I also show you a wooden microscope which unfortunately was almost destroyed by the furniture dealer from whom I got it. He pulled the pasteboard tubes out, glued the sliding part together, and gave it to his wife to use as a candlestick! The construction of this microscope was peculiar; it consisted of three lenses, the first being of very short focus in proportion to its diameter. The focus of the combination was altered by varying the distance of the back lens from the others. I put it together in a temporary fashion and found it worked fairly well.

I had also intended to show you a compound non-achromatic microscope of English manufacture which I have, as it has several features of interest, but it has been mislaid, and I must content myself with describing it. The objective is of peculiar construction, and as I have an achromatic objective by Hartnack very similar, it will be worth consideration, the more so as I do not remember seeing it described in the leading books dealing with the subject. The objective is a doublet. The first glass is of short focus (half inch), and the second of one and a half inch, and of large diameter, the separation of the two being nearly the focal distance of the larger lens. Both the lenses are double convex and of crown glass. The Hartnack lens consists of two plain convex lenses. The first is of half inch focus and the second is of one and a half inch focus, and larger diameter as in the former instance, but the separation of the lenses is less, being only about an inch. The resemblance of the two is striking, and in each case the characteristics of their performance are alike, allowing for the superiority of the achromatic combination. These characteristics are—a large flat field and great penetrating power or depth of focus. I drew the attention of a practical optician to the peculiarity of the old lens, and, like myself, he was quite unaware that such a construction was in use, much less that so distinguished an optician as Hartnack had adopted it.

The eyepiece of the old microscope was also of interest, as it is compensating in its action. It consists of three plano-convex lenses, two of which work together as the eye lens, and the third forms the field lens. A sliding tube allows the eye lens to be separated from the field lens, and admits of an adjustment to suit the length of tube employed, which is, as in the Hartnack and other instruments, of a sliding form. It is well known that an objective constructed for a short tube does not work so well with a long one. It is also understood that eyepieces, to work to a nicety, should be adjusted for the length of tube, so that something in the way of precise information should be engraved by the opticians upon their eyepieces and objectives. An Austrian optician sets a good example by engraving upon some of his objectives the length of tube required and the angular aperture of the lens. He also constructs compensatory eyepieces, but of their nature I do not know anything. As an example of how things are managed on the Continent, I might mention that the catalogue of the Viennese maker contains descriptions of instruments capable of being used vertically only, and is innocent of anything so sensible as a binocular microscope, yet he uses the Jena glass, and in other respects does not seem behind the age. After this digression I had better return to the old microscope, of which I must now take leave, with a compliment to its unknown maker, for a better non-achromatic instrument was probably never constructed. Before considering the achromatic microscope, it will be as well to speak of the eyepiece. The most usual form is the Huygens, an example of which you see. It consists of two plano-convex single lenses placed at a distance of half their focal length; a stop is placed about half way, and upon the correct placing of this stop depends the correction of the chromatic aberration. Another good form of eyepiece is the Ramsden, or positive eyepiece. With this the image is formed outside the combination, and it is thus available for micrometer purposes. The correction for colour is not very good, but the difficulty is obviated in the example by Smith and Beck, which I now show you, as it has the eye lens achromatised.

According to Andrew Ross, if both lenses were achromatised it would

the by far the best eyepiece of all, but, as every defect in the field lens is seen, opticians prefer to make it a single lens, which costs little to manufacture, and can be sacrificed if at all defective. Eyepieces of various powers are employed, but, as a general rule, the lower the power the more accurate and pleasing the performance. I have seen it advised to use high eyepieces and low powers, but this is contrary to the accepted rule. The first achromatic object glass for microscope was constructed, at the suggestion and expense of Dr. Goring, by Mr. W. Tully in 1824. In its earliest form it consisted of a double concave of flint placed between two convex lenses of crown and Dutch plate glass. As will be seen by-and-by, the triplet form of lens plays a most important part in our modern instruments. The first lens, consisting of a double and equally convex lens of plate glass and a plano-concave of flint was constructed by M. Chevalier upon the principles laid down by the mathematician, Euler. These lenses were combined in the doublet form, and excessively stopped down, but Dr. Goring, who discovered the principle which governs the penetrating power of lenses, removed the stop, and was then enabled to show the ordinary test objects with them. Since then three and four sets of lenses have been combined, but the principle is now accepted of having as few lenses, and consequently reflecting surfaces, as possible.

The greatest improvement ever introduced into achromatic object glasses is the invention of the single front by Mr. Wenham in 1850. His first attempt was upon an $\frac{1}{2}$ object glass, in which he endeavoured to replace a triple front with a single one. In the same year Mr. Lister, experimenting on high powers, introduced the triple back, which allowed perfect correction to be obtained with the most extreme apertures. Mr. Wenham soon after this invented an object glass ($\frac{1}{4}$) with triple back and single front, which, notwithstanding the advances made, is still esteemed an excellent lens.

The first attempts with single fronts were comparative failures, owing to the front lens being too thin, the correction for spherical aberration depending upon the thickness of the front lens. The magnifying power is almost entirely obtained from the front lens, the middle and back combinations having merely corrective influences. It is important that the separation of the combinations should be such that all the lenses come to a focus at the same point, otherwise the image will not be hard and clear. It is for this reason that the longest focus lens is placed at the back.

The usual forms of object glasses are as follows:—Low powers, 3, 2, and $\frac{1}{2}$ inch, consist of two pairs of lenses, usual form, double convex and plano-concave flint, with the convex uppermost for back lens. Mr. Martin, of South Shields, deviates from the general practice, and employs, with great success, a form of construction similar to that adopted in rectilinear photographic lenses. He employs a light flint, .364, and thus avoids the tendency to rust which exists in heavy flints and many forms of Jena glasses. It is this tendency to rust which makes the most desirable samples of the Jena glass unreliable, sometimes even when encased between two pieces of crown glass.

For the one and two-thirds of an inch objectives the front is of the same form as in the lower powers, but the triple combination is best for the back lens.

The construction of the half inch and all higher powers are the same. The best form is the single front, middle pair, and back triple. The front triple is not often made now, but I have seen very good lenses of this form. There is not much difference in practice of opticians, so far as general lines are concerned, the difference in excellence being rather one of skill than of principle. I should have added that from the half inch power upwards the correction collar, by which the aberration introduced by the cover glass is corrected, becomes a necessity. It would be clearer to understand if I say that opticians correct their lenses for use with cover glasses of about one one-hundredth of an inch thickness, and a correction collar is necessary when other thicknesses of glass are employed, or a cover is dispensed with. There are two forms of constructing these correction collars—one where the front lens is separated from the two other pairs, and another where the front lens is fixed and the rest of the combination moves. The latter should be the best construction, as the object is not thrown out of focus.

It may be worth while to mention that some opticians understate the focus of their lenses, so as to lead the public to believe that their performance for the focal length is better than it really is. The practice is not an honest one, because, other things being equal, the lower the power of the object glass the better. The lenses, of which I show you some minute examples, are rough ground with emery powder, of which that known as Naros is the best. The polishing is done by means of putty powder, or oxide of tin, and crocus, or peroxide of iron, also with jewellers' rouge, which is extensively used. Here are some specimens of glass employed, and an example of extra dense flint which has rusted, as you see. Mr. Martin, who has been good enough to supply me with these and also the grinding tools which I shall show you, recommends flint .364, and French plate crown, which he finds works even better than Chance's white crown. With these materials he obtained in a three-inch telescope perfect correction, with definition hard and most satisfactory. He also employs the French plate crown in his microscopic objectives. I may mention, in passing, that the usual construction of a telescope objective is a double concave of light flint united to an equi-convex crown. The lighter the flint the deeper the curve to obtain correction. In small telescopes the Herschel form of objectives is best.

I have had no practical experience in the employment of the microscope or telescope for photographic purposes, and I trust you will kindly make good the deficiency of my paper in this and other respects. I shall, however, venture upon a few words more before turning to photographic lenses proper.

In the employment of the microscope in conjunction with the camera, the eyepiece is generally discarded, but this is not necessary. The best form of eyepiece is the orthoscopic, which gives a larger field than Huygen. Projecting eyepieces are also constructed for photographic work. Many opticians correct their object glasses for photographic use, and Messrs. Beck state that theirs may be used, as the chemical and visual focus almost coincide.

I find my paper running rather long for the time at our disposal, so, if you will allow me, I will conclude the microscopic section by showing you a double reflecting prism, as used in the binocular microscope to throw the image into the second tube. It is made of white crown glass. With regard to photographic lenses, I shall, with your kind permission, postpone their consideration to a future evening, when they may, perhaps, have the advantage of being treated by an abler and more experienced hand than myself.

I wish, however, to show you Dallmeyer's new landscape rectilinear, also a single stereo lens by Lerebour & Sécretan, constructed about thirty years ago, which is made to work at $f/8$, an aperture which a year or two ago was regarded as outside the capacity of single lenses, and when introduced was looked upon as an advance in lens making. I have also here a stereo doublet by Ross, which was formerly the property of the late Prince Imperial. Speaking as an amateur, I venture to say that a doublet constructed as this is, to cover with a large stop a quarter-plate, is the best and most useful small lens for the amateur. Although it has six reflecting surfaces, its performance is almost, if not quite, equal to the rapid rectilinear, and it has an aperture equal to the extra rapid portrait lenses.

I will now show you two lenses by Grubb. The first is an example of his patent aplanatic view lens, in which the flint and crown elements are reversed in position to that ordinarily given. The second lens is a 2 A portrait lens, which, as you see, has been very badly used, and if you examine the surface with this Coddington lens you will observe that the surface is eaten in patches by rust, the result of the instrument being left in a damp place for a long time. As a deviation from the spherical surface of $\frac{1}{8}$ of an inch interferes with the formation of the image, you readily understand that the Grubb lens, which costs about five pounds, is not now worth five shillings. As the hour is late I must now conclude, thanking you for your patient attention to my paper and the interest you have shown in the subject.

H. C. HENRY.

LORD RAYLEIGH ON EXPERIMENTAL OPTICS.

V.

LAST Saturday Lord Rayleigh stated that Newton tried to explain the colours of all objects as due to phenomena presented by thin plates, but that, nevertheless, the colours of ordinary bodies are not analogous to those produced by thin films; the colours produced by such films are far from being the pure colours of the spectrum, whereas in nature colours are often seen in pigments, and otherwise, not inferior to those of the spectrum itself. That is one reason opposed to Newton's idea, and, perhaps, a still better reason is that, if colours are due to interference, the light missing in the reflected beam ought to be seen in the transmitted beam. This leads to the subject of the absorption of light, and the conversion of coloured rays into heat; a subject which even now is not well understood. Perhaps the nearest approach to an explanation may be given by selecting in illustration the action of coloured gases upon light; let blue light, for instance, fall upon the yellow gas, chlorine, the blue rays are neither reflected nor transmitted, but it can be proved that in proportion to the action of the blue light the gas rises in temperature, so that the energy of the blue rays is transformed into the energy of molecular vibration. It is supposed that the molecules thus have their vibrations increased, but the absorption goes on as long as the light falls on the gas, so we must suppose that the molecular motion is in some way disturbed; one molecule perhaps strikes against another, and the result becomes sensible as heat. In this way the loss of energy by the light may be explained.

A coloured liquid, according to its thickness, gradually attenuates the light passing through it. Absorption takes place also in other ways; the colours, for instance, of metals, such as gold and copper, are not due to absorption acting in the ordinary way, but they are due to absorption nevertheless; after the light reaches a certain depth, the metal begins to reflect in a more strenuous manner. Something analogous takes place with sound when it falls upon a haystack; the sound-waves meet with resistance increasing with the depth, and are then reflected by the hay. Aniline dyes show in thin layers a high degree of colour. Lord Rayleigh here passed light from the electric lamp through a plate which had been coated with a pinkish-red aniline dye—name not mentioned—which had been dissolved in collodion and applied to the plate thereby; this film reflected green light in an abnormal way, that being chiefly the light which could not get through the plate; by the suitable interposition of a

polarising prism, the light to which the dye was most intensely opaque was more particularly isolated upon the screen. Permanganate of potash solution intercepts green rays strongly, and gives a spectrum containing a prominent series of bands; the reflected light when spectroscopically examined also reveals the presence of these bands, and it is rich in green light.

As light will pass through a vacuum, it becomes necessary to assume a medium by which it does so; this medium is called "ether," a name which in this case means nothing in particular. When light passes through glass or water it might be supposed that the glass would take up the motions from the ether on one face and give them out again to the ether on the other, but then it is found that the velocity in glass is much quicker than would have in such case been expected; the velocity of light is reduced in the glass in the ratio but of three to two; the ether must be regarded as taking a leading part in the conveyance of light through glass, and colour considerations lead to the same conclusion. In a vacuum, so far as is yet known, all kinds of light move with the same velocity, and observations of different variable stars have furnished evidence pointing to the same conclusion; take the case of a variable star which disappears and reappears at known intervals; if red light, for instance, travels faster than blue, the star should look red for a short time after its moment of reappearance; no change in the colour of their light is shown by such stars, either when they reappear or disappear, and it has been calculated that an exceedingly small difference in the rate of propagation of lights of different colours would be detected did it exist. Sound-waves of all kinds are transmitted through air with the same velocity, and there is no mechanical reason why it should be otherwise. The vibrations which take place in a rigid body, such as a board, bear most resemblance to those of light.

To show a certain amount of parallelism between the phenomena of sound and those of light, Lord Rayleigh then proceeded to produce some sound-shadows. His sounding instrument was made on the bird-whistle principle, but so high and shrill as to be inaudible by means of human ears; it was actuated by a steady supply of air from a bellows. The indicator was a sensitive flame about a foot long, which shortened itself to about six inches in length when suitably acted upon by the sound. He then proceeded to prove that some of the waves of sound from the whistle neutralised each other, or produced sound-shadows; by the use of suitable discs and rings of zinc, to cut off some of the waves producing the neutralisation, the flame was more vigorously influenced than when nothing at all was placed between it and the whistle. In one experiment he placed a circular disc of glass, over a foot in diameter, between the whistle and flame, and proved that opposite the centre of disc plenty of sound reached the flame, but half an inch or so away from this acute central position was a broad sound-shadow, in which the flame was uninfluenced. The whistle was three or four feet in front of the glass plate, and the sensitive flame three or four feet behind it in this experiment. A French philosopher once brought what he supposed to be a crushing argument against the wave theory of light; he said that if that theory were true, in the centre of certain circular shadows there should be a spot of light; Fresnel, seeing the force of the argument, tried the experiment, and discovered the spot of light to be actually there. By suitably experimenting in an otherwise darkened room, with a beam of light and a threepenny piece, this spot may be seen in the centre of the shadow thrown by the coin. The wave theory, in fact, explains all the known phenomena of light, and made known the existence of some before they were first seen experimentally.

Lord Rayleigh next produced Newton's rings in an unusual way. Light from the lamp was passed through a small hole, then received by a glass concave mirror silvered on the back, and so placed as to send the beam of light back through the hole from which it had issued in the front of the lamp; the face of the mirror had a little dried milk upon it; Newton found that dust would answer the purpose. On the white cardboard surrounding the hole Newton's rings were brilliantly visible.

PSYCHIC PHOTOGRAPHY.

THERE seems to be for the present a lull in the interest displayed in this department of photography, if department it may be termed.

A Birmingham friend, Mr. Edwin C. Middleton, who in our interests kindly undertook to interview the high priestess of psychic photography in that city, has sent as a graphic account of his visit, from which we shall make extracts. Having in course of the interview asked to see some of the negatives produced under Miss Power's supervision, "A dozen or more," he says, "were placed in my hands; they were free from retouching, and very varied; in some, the manifestation was a mere dab or patch, without the faintest aspect of a face or form; in others, a face was certainly discernible, and one at least was a three-quarter-length figure about half an inch long, and appearing above the head of the medium. One showed a head very much reminding me of a well-known engraving. And in the case of another medium, the one spirit had apparently visited us twice—looking to the left in one instance, and to the right in another, but wearing the same spectacles on each occasion. Noticing that in all the cases where a form could be traced that Miss Power herself was the medium, I inquired as to the exact method of procedure, and who made the exposure. The proceedings are as follows: A plate is placed in the dark slide; the sitter,

or medium, takes her place and sits for *forty minutes* in absolute darkness; during this period the 'spirit' impresses the plate; a few inches of magnesium ribbon are now burned, that the living sitter may be included, and development ensues. Sometimes results are satisfactory, sometimes not; there is great uncertainty. 'And who makes the exposure, Miss Power?' I inquired. 'Oh, an artist of my acquaintance.' 'Does he remain present during the period of darkness?' 'Oh, yes, all the time.' 'You have never had any result in which you could recognise a "spirit" except when he has been present?' 'No,' replied Miss Power.

"How did you become acquainted with this artist?" This question brings forth a long explanation as follows:—Miss Power wished to have lessons in photography, appealing in vain to one or two professionals. Miss Power proceeds: 'We formed a circle, Mrs. E. being the medium. We received a communication from the spirits advising me to appeal to Mr. P., an artist. I called upon him and he seemed almost to expect me. He undertook to instruct me, and arranged to come on the following Tuesday. I had a number of friends present and he disappointed us. However, on the following Tuesday he came most unexpectedly; no one was here. He would not permit me to send for any one, and proceeded at once and obtained results.' 'Where does Mr. P. reside?' I inquired. 'Park-road, Hockley.' 'And where does Mrs. E. reside?' 'Lodge-road, Hockley,' replied Miss Power. For the information of those unacquainted with Birmingham I may say Park-road runs out of Lodge-road, while Miss Power resides at Ashted on another side of the town. 'Are you willing to make any demonstrations this evening?' 'No,' replied the lady. 'On what grounds?' 'My spirit friends have advised me not to; they tell me I have made a mistake in rushing into print. That while the matter is so uncertain in results it would be better that I should not attempt demonstrations before strangers and sceptics.' 'When will you attempt a sitting?' I inquired. 'This month (March) is an unfortunate one for me, and I do not think of attempting anything before strangers.' 'When shall you be disposed to do so?' 'Well, not before June, I think.' And finding entreaty of no avail, the interview came to a somewhat abrupt termination.

"I next made my way to Park-road, and visited Mr. P., the 'artist' operator; my feelings experienced somewhat of a shock to find he described himself as a 'sign writer.' 'You take spirit photographs, I believe?' 'Yes,' replied the artist, who, probably to show his contempt for the east winds, had boldly dispensed with collar and necktie, and whose love of fresh air was further exemplified by the quantity of stocking to be seen fitfully gazing through the somewhat numerous ventilators in the toes of his boots. 'Have you any examples?' 'No.' 'Could you produce some in my presence?' 'Yes.' 'Will you do so?' 'All my apparatus is at Miss Power's.' 'If I will provide all requisites and conditions will you produce "spirit photographs"?' 'I will try.' 'You do not always succeed?' 'No; I have tried for five weeks at a time and not been successful.' 'You might do so again?' 'Yes, certainly.' 'When will you try?' 'Next Wednesday, if you like; but I have wasted a deal of time already.' 'I will pay you for any time you may lose.' This offer, I may say, was scornfully rejected; although at the close of the interview there was an oblique reference to a large family.

"I do not purpose wasting further time on what I am firmly convinced is a fraud—and to which I believe Miss Power herself is a victim. Since my interview she has written suggesting I join the 'Spiritual Evidence Conference,' to which a subscription is payable. And the practical bent of Miss Power's mind is further illustrated in the suggestion, most delicately thrown out, that she has 'apartments to let,' and if, Mr. Editor, you do know a young man who in addition to other comforts would like a nice spiritual home, don't forget 92, Ashted-row. The name to inquire for is Miss Power.

"As a matter of history, I believe the first spirit photographs in this country were produced by either F. Parkes or Fred A. Hudson, who is, or was, a photographer at Notting-hill. The latter gave no guarantee as to the origin of the photographs, and Mr. Maskelyne says that he made every person sign a book agreeing to ask no questions. It may be well to mention that in 1875 three persons were sent to prison in France for taking and, I suppose, charging for spirit photographs."

Editorial Table.

PROCESSES OF PURE PHOTOGRAPHY. By W. K. BURTON, C.E., AND ANDREW PRINGLE.

New York: The Scovill and Adams Company, 423, Broome-street.

It has been known to us for some time that the two capable men who are named above, Messrs. Burton and Pringle, have been engaged in writing a work on photography, and we are at length gratified by a perusal of it, a perusal which has afforded us high satisfaction, as, indeed, anything emanating from such a source could scarcely fail to do. There is but little history, no attempts at "fine writing," and only a modicum, if any, of theorising; but there is a perfect wealth of solid, practical information of just the very nature in which photographers delight, and which, with certain tables, including those relating to weights, measures, thermometric values, enlargements, and so forth, reach 200 pages. From the preface we learn that at first the authors' MSS. ex-

tended to a very considerable length, and treated photography completely as theoretical, practical, and artistic; but circumstances caused them to abridge their work and produce "a book less complete and, perhaps, less interesting, but, as we hope, more generally useful, not only to amateurs and beginners, but also to those who desire authentic instructions and formulae for everyday work."

We are so nearly at one accord with the authors in all they say as to afford no opportunity for offering any critical remarks on their work beyond an expression of unqualified praise; we may, however, give our readers a rough synopsis of its contents. Apparatus of course, and this largely from the American point of view, seeing the book was doubtless primarily intended for American readers; the dark room and its fittings; wet and dry collodion processes, both by bath and emulsion; gelatinobromide emulsion, in every degree of rapidity from slow to extra rapid; the development, intensification, or reduction of negatives; printing paper of every nature, whether for printing-out or developing, including platina and carbon paper; toning, enlarging, lantern transparencies, and the treatment of residues, complete a volume of sound information, and noticeable for its abnegation of anything appertaining to "shop."

We now give an extract to indicate the practical style adopted, and we select one from chapter xii., *The Camera in the Field*. After speaking of setting up the camera to take a landscape, the selection of a stop, and the adjustment of the focus, our authors go on to say:—

"If the subject includes parallel, vertical, or horizontal lines, as in architecture, some further considerations require notice, and the following remarks apply particularly to cases where the architecture either fills a large portion of the plate or falls near the edge of the picture. In such a case the first necessity is that the camera shall be dead level. But, possibly, the whole of the building will now not 'come into' the plate. The first expedient is to go as far away from the building as possible. Failing that, if the top of the building will not come into the field, the front of the camera must be raised as far as it will go without letting light into the camera. Failing that, the vertical position of the plate may be tried by reversing the back or turning the camera on its side. If this is not satisfactory the camera must be tilted upwards, always supposing we have only one lens. A shorter-focus lens might, of course, remove the difficulty; but tilting the camera upwards will at once cause the straight lines of the building to be 'distorted,' and in that case we must use the swing back. The lower part of the swing back must be drawn out or the upper part pushed forward till the ground glass hangs vertical—parallel, that is, with the lines of the building, and in this case a very small stop is required, for reasons into which we cannot enter here.

"The swing back is very frequently totally misunderstood and shamefully abused, the reason being that photographers do not know, or at least fail to realise, that the swing back has two uses totally distinct from each other. The uses of the swing back are: (1st), that suggested a few lines higher, viz., to prevent distortion when the camera is tilted; and (2nd), to aid in getting into simultaneous focus a near object and a distant one. On (1) we have said all that seems necessary; on (2) a few words may not be wasted. The focus for an object close to the lens is, as everybody must have observed, further back or farther from the lens than the focus for an object at a considerable distance away; so that with the ground glass hanging vertical when a distant object is in focus the image of a near object is in front of the focus and blurred. If we focus on the middle distance, or on an object (say) fifty times the focus of the lens distant from the camera, both the distance and the foreground are out of focus, the distance on the ground glass being behind the best focus and the foreground in front of its best focus. Plainly, therefore, if our swing back works on its centre, as every swing back ought to do, and if we pull the top of the swing back backwards we shall also push the bottom of it forward, so that the middle distance will remain in focus and the foreground and far distance will each find its proper focus. With a central swing this is plain enough, but with a swing back working from the top on a pivot at the foot we are very apt to make the general focus far worse than it was. With such a swing back, which is usually a swinging of the whole back of the camera, we must either focus on the distance and then pull back the upper part till the foreground is focussed, or we must pull the top towards us first and try to focus thereafter, a very awkward and uncertain proceeding at the best. The first use of the swing back—to prevent distortion—necessitates the use of a small stop; the second use, to a great extent, obviates the necessity for a stop, or, at any rate, permits of the use of a larger stop. In all cases the focus should be examined after the use of the swing back."

The volume forms No. 29 of *Scovill's Photographic Series*, and is admirably printed in that fine style so characteristic of the best American books. Its intrinsic merits, not less than the reputation of its authors, will ensure it a large circulation. It sells at two dollars.

SUTER'S NEW SERIES OF PORTRAIT APLANATS.

J. R. Gutz, 19, Buckingham-street, Strand, Agent.

We have already and recently spoken of these aplanatic lenses. Since doing so we have had a considerable experience with one of them for which special features have been claimed.

By comparison with a lens of similar dimensions and focus, of the class that was made by M. Suter over a year ago, we find a considerable difference, and, we may add, a great improvement in the more modern one. This is attributable to the employment of the new Jena glass, which in this instance is entirely free from colour, whereas in those of previous manufacture the glass was seen to possess a tinge of colour when laid down upon a sheet of white paper; not much it is true, but still perceptible. The elimination of this from the new portrait aplanats causes them to work much quicker with the same aperture. It was, we suppose, difficult to obtain flint glass possessing a density sufficient to enable a lens of large angular aperture to be made in which there was not a little colour, or, if colourless, which would remain so; but thanks to recent advances this may now be considered a thing of the past. Mr. Gutz informs us that the glass in this class of lens, so far from possessing the density of that of yore, is very light, that is, in its specific gravity. But the present has another advantage over the past one; the oblique pencils are by it projected farther than the other, so that the flatness of field with a large aperture is considerably extended.

That special production which calls forth these remarks is the *D. Rapid* /*planat* of ten inches focus, which with its full aperture, equalling *f-5.5*, gives a degree of definition susceptible of being magnified several times without showing any falling off in the enlargement. Comparing this with the previous production already referred to, we find that M. Suter has made a decided advance, and, as in the former one, it is free alike from distortion and from a flare spot when used with a stop.

The flange and diaphragms are made on the system recommended by the Photographic Society of Great Britain as a standard.

RECENT PATENTS.

PATENT COMPLETED.

IMPROVEMENTS IN THE PRODUCTION OF COLLODION PHOTOGRAPHIC FILMS OR SURFACES OF EXALTED SENSITIVENESS.

No. 7044. RICHARD NORRIS, 3, Birchfield-road, Aston, near Birmingham, Warwickshire.—May 11, 1888.

THE photographic process, commonly called the collodion process, has of late fallen largely into disuse in consequence of the higher degree of sensitiveness possessed by the dry gelatine plates or films now commonly used in the practice of photography. Collodion possesses some advantages over gelatine as a photographic vehicle, which advantages have hitherto been more than counterbalanced by its inferior sensitiveness.

The object of my invention is to increase the sensitiveness of collodion photographic films or surfaces, and consists in the methods hereinafter described of preparing the said films or surfaces, whereby they are made equal or superior to dry gelatine plates in their sensitiveness to light. These methods may be designated the alkaline and acid bath and emulsion processes.

I will describe first the alkaline bath process. In this process I add the silver salt to the collodion instead of impregnating the collodion, as is usual, with a soluble iodide, or bromide, or other haloid salt or salts, because by this method of procedure a greater range in the selection of the haloid salt or salts to be used as a bath is secured, for many of these salts are insoluble in a mixture of ether and alcohol, which is the menstruum in which guaiacolin (pyroxyline) is dissolved to make collodion. To make one ounce of such a collodion I dissolve seven grains of pyroxyline, made at a temperature of about 200° Fahr., in a mixture of two drachms of ether and one drachm of alcohol. I then take twenty-six grains of very finely powdered silver nitrate and mix it in a test tube of suitable capacity with eighty drops of glycerine, and stir it continuously with a glass rod till most or all of the silver nitrate is dissolved. I then add gradually to this solution five drachms of absolute alcohol, and finally add by degrees the whole of this to the solution of pyroxyline. By the use of glycerine instead of alcohol for dissolving the silver salt the said salt is most conveniently introduced into the collodion; alcohol may, however, be used for that purpose.

Glass plates, paper, or other surfaces may be coated with the prepared collodion described and then submerged in or floated upon a solution of the soluble haloid salt or salts to form a film containing iodide, bromide, or chloride of silver, or mixtures of these.

I will describe my process in connexion with a photographic film on a glass plate.

Having coated the plate with collodion charged with a salt of silver, nitrate of silver, for example (which collodion may be called "argentic collodion"), I submerge the coated plate in a bath of iodide, bromide, chloride, or other compound haloid salt of potassium, sodium, ammonium, or the like, for a period varying from five to forty-five minutes. Films produced in such baths are much more sensitive after the bath has become charged with ether and alcohol, hence, in preparing the said films, I add ether and alcohol to the bath of haloid salts.

A bath of the following composition answers well in practice:—

Potassium bromide, from thirty-five to seventy grains; distilled water, half an ounce; methylated alcohol of specific gravity .830, half an ounce; methylated ether of specific gravity .717, thirty-six minims. The longer the plate or film remains in such a bath (within the limits I have given, namely, from five to forty-five minutes) the more transparent and sensitive it will become. It will also undergo those well-known molecular changes which modify the tint of the silver haloid salt to transmitted light from ruby to blue and green. The temperature of the bath should be about 76° Fahr. The plate having remained

a suitable time in the bath (according to the sensitiveness desired) it is withdrawn and washed with water, and submitted to the action of a dilute alkaline solution, such as a solution of potash, soda, ammonia, or the alkaline salts of these and allied bases. The method I usually adopt is to dissolve two hundred and forty grains of caustic potash (hydrate) in eight ounces of distilled water as a stock solution; of this I take forty minims and add it to eight ounces of water to make the alkaline bath. The plate is allowed to remain in this bath from ten to fifteen minutes and is then transferred to a solution of gelatine containing, preferably, forty grains of dry gelatine to a pint of water, in which it may remain from fifteen to forty-five minutes; it is next passed into a dilute solution of a soluble iodide or bromide, such as iodide or bromide of potassium, ammonium, sodium, or the like, in which it may remain from ten to fifteen minutes. The iodide bath, which is preferable, may be thus prepared:—Iodide of potassium, eight grains; water, eight ounces; half a drachm of this solution is added to eight ounces of water to make the bath.

The object of this last-described treatment is to convert the silver bromide, chloride, or chloro-bromide into corresponding compounds of iodo-bromide, iodo-chloride, and iodo-bromo-chloride of silver. These iodine compounds can only be successfully produced by this method of displacement, for if a soluble iodide is added to the bath resensitising with silver nitrate becomes necessary. The employment of the iodide, on the other hand, confers great advantages, both as to sensitiveness, freedom from fog, and susceptibility of development. The plate after the treatment described may be washed in water. Having at this stage acquired its full sensitiveness, it may either be used at once as a wet plate or be saturated with any of the well-known preservatives, such as gum, gelatine, dextrine sugar, or analogous substances, and either be dried spontaneously or by the suitable application of heat. The preservation does not either exalt or diminish the sensitiveness.

It is scarcely necessary to remark that all the processes described, as well as those hereinafter described, excepting the preparation of the collodion and solutions, must be conducted in a low non-actinic light.

In another of my improvements, which I have referred to as the acid bath process, I make collodion after the customary method, that is, I charge it with iodides, bromides, or chlorides, or mixtures of these salts, soluble in alcohol and ether. I submerge the plate or surface coated with such prepared collodion for periods varying from five to forty-five minutes in a nitrate of silver bath charged with salts which are compounds of haloid silver salts with silver nitrate; that is, iodo-nitrate of silver, bromo-nitrate of silver, chloro-nitrate of silver, or compounds of these, such as iodo-bromo-nitrate of silver, iodo-chloro-nitrate of silver, and iodo-bromo-chloro-nitrate of silver. I form these salts in their crystalline state and add them in quantities sufficient to saturate the silver solution used as a bath. The full sensitiveness conferred by baths of the kind last described is only obtained by the use of unusual proportions of nitric acid. From forty to one hundred minims of dilute nitric acid of specific gravity 1.101 to each ounce of bath solution. A larger proportion confers higher sensitiveness but it produces rottenness of the film. A bath of the kind referred to may have the composition and may be prepared as follows:—Silver nitrate, five hundred and sixty grains; dilute nitric acid, six hundred and forty minims; distilled water, eight ounces; add the acid to the water and dissolve in it the silver nitrate, lastly add iodo-bromo-silver nitrate or allied compound silver salts to saturation.

These compound salts of silver haloid and silver nitrate are prepared by adding silver iodide, bromide, or chloride, or silver iodo-bromide, or silver iodo-bromo-chloride to concentrated but solutions of silver nitrate to saturation. When the solutions become quite cold the compound salts will be deposited and may be collected and transferred to the silver solution prepared for the bath. This solution should then be kept in a warm place for several days and shaken or stirred at intervals to insure saturation. The film or plate on removal from the bath is washed with distilled water and, as in the former process, passed through the gelatine and iodide baths, after which it may be washed in water and used as a wet plate or preserved, as in the manner hereinbefore described, dried, and used as a dry plate. In this process the alkaline bath is omitted.

The ultimate sensitiveness of the photographic surface obtained will be related both to the length of time the film is in the bath and to the temperature of the latter, which may be used from 84° to 150° Fahr. These films progressively undergo the well-known molecular changes from ruby to blue by transmitted light while in the silver bath.

My invention further consists in the preparation of photographic plates or films by means of collodion emulsion, inasmuch as these emulsions, whether prepared with the soluble bromide or the silver nitrate in excess, may have exalted sensitiveness conferred upon them by the methods described in the foregoing bath processes. In an emulsion with soluble bromide in excess the emulsion or film is treated, after washing, with the alkaline bath or wash, and subsequently with the solutions of gelatine and alkaline iodide, and finally preserved and dried, as in the previously described processes.

In the case of an emulsion in which the silver nitrate is to remain in excess, the emulsion must be prepared in the first instance with a solution of silver nitrate saturated as in the acid bath process with iodo-nitrate of silver, iodo-bromide or chloride of silver, or mixtures or compounds of these salts.

After washing the emulsion the film must be treated with solutions of gelatine and iodide and washed, dried, and preserved as in the preceding cases.

In the preparation of an alkaline emulsion, that is, one with the soluble bromide in excess, the greatest sensitiveness is obtained by the use of the bromides of the alkalies rather than those of the earths and heavy metals.

Plates or films prepared by any of the processes hereinbefore described, are equal, if not superior, to gelatine plates in their sensitiveness to light. They may be readily developed with the ordinary chemical developers, such as ferrous oxalate of potash, or alkaline pyrogallie acid, or hydroquinone, and fixed either with solutions of hyposulphite of soda or cyanide of potassium.

The exposing of plates treated according to my invention in the camera obscures, their development, fixing and drying, and complete preparation for printing from may be effected in about a quarter of an hour.

In the description of my invention hereinbefore given I have indicated the particular materials which I prefer to employ, and the proportions which I

have found to answer well in practice. I have also described the best methods with which I am acquainted of conducting the processes involved in the practice of my invention. But I wish it to be understood that I do not limit myself to the use of any particular materials, as materials chemically analogous to those I have described may be employed, neither do I limit myself to the strengths indicated of the solutions employed, nor to the precise order of their application, nor to the temperatures at which the processes are conducted.

Having now particularly described and ascertained the nature of my invention, and the manner in which the same is to be performed, I declare that I claim as my invention of "Improvements in the production of collodion photographic films or surfaces of exalted sensitiveness:"—1. The method herein described of producing a silvered or argentised collodion containing such an amount of silver nitrate as will form, when treated with an aqueous solution of iodide, bromide, or other analogous salts of potassium, sodium, or ammonium, or other base, a film or surface of sufficient thickness and density to give intense images and insure freedom from halation substantially as described. 2. The improvement of the sensitiveness of such films or surfaces by the addition of alcohol and ether to the before-mentioned aqueous solutions of iodide, bromide, or other analogous salts of potassium, sodium, or ammonium, or other base substantially as described. 3. The use of alkalies, alkaline carbonates, or allied salts as sensitizers of films or surfaces or emulsions which have been produced in an excess of soluble haloids substantially as described. 4. The use of a weak solution of gelatine, not as a vehicle or preservative, but as a direct sensitizer of the haloid silver salts substantially as described. 5. Treating the film or surface with very dilute solutions of iodides and bromides to convert the bromides or chlorides of silver in the film or surface, or in the emulsion into compound salts of iodo-bromide, or iodo-chloride or iodo-bromo-chloride of silver possessing more exalted sensitiveness, and finishing the film or surface substantially as described. 6. The employment of collodion charged in the usual way with haloid salts of potassium, sodium, ammonium, and the like, and treating the film or surface obtained by the use of the said collodion with a solution of silver nitrate charged preferably to saturation with iodo- or bromo-nitrate of silver or compounds of these and other analogous salts or salts of silver and containing free nitric acid substantially as described. 7. The employment of the materials and processes referred to in the preceding claims to the production of emulsions for the formation of photographic films or surfaces substantially as described.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

MARCH 28.—Mr. C. H. Cooke in the chair.

Mr. A. Cowan exhibited some carbon film cloud negatives sent to him by Mr. Nisbet and taken by Mr. W. Green, of Berwick-upon-Tweed.

The CHAIRMAN said that the cloud negatives were good ones, but a disadvantage in commercial cloud negatives is that it is awkward to see pictures by different persons in exhibitions having the same clouds.

The HON. SECRETARY exhibited some photographs, also by Mr. W. Green, of ornithological and natural history subjects; he said that the one representing sea birds on the Bass Rock was particularly good.

Mr. W. H. HARRISON said that having been asked by the previous meeting to obtain some information about the concentric two-wick paraffin lamp used in light vessels, he had seen its inventor, Sir James Douglass, chief engineer to Trinity House, who had kindly shown him the lamp in action. The vital feature of the lamp is that it causes three air currents to impinge upon the outer flame a little above the burner, at three different but closely adjacent levels, the effect of which is to compress the two flames, so as to give increased light in a smaller space; the base of the glass chimney of the lamp is therefore not bulbous, as in the instance of those of ordinary paraffin lamps. Another feature of the lamp is that the level of the oil is always at a fixed distance below the top of the burner, and Sir James says that this level should vary with the flashing point of the paraffin used; with oil having a flashing point of 256° Fahr., as used by Trinity House, the level of the oil is close upon half an inch below the top of the brass burner; when the oil falls a little below this there is a loss of light; when it rises a little above it, the flame is more unsteady, and at a still higher level the oil catches fire. With concentric ring gas lamps, made upon the same principle, exactly twice as much light is obtained from a given quantity of gas, as with the standard London Argand burner. Trinity House uses such oil and gas burners of different sizes; the largest have ten rings. It might be well to see whether a three-ring lamp will give too large a flame for the optical lantern. The lamps of all sizes are specially constructed to keep the brightest part of the flame constantly in the centre of the optical system or parabolic mirror used for the distribution of the light. Several firms manufacture the lamps and burners by contract for Trinity House, and he (the

speaker; afterwards called upon one of them, who told him that the burners are not on sale to the public, but that if they could be utilised for the optical lantern or other purposes, he had no doubt that Sir James would allow them to be issued, adding that the two-ring gas flame gives only about twenty per cent. less light than the two-ring paraffin flame, and that the oil should not vary for practical purposes more than a quarter of an inch from its proper level, although with the delicate photometrical instruments used at Trinity House, degradation is seen to begin with variations of about half that amount. Sir James told him (Mr. Harrison) that his only reason for patenting the lamp was, that if he had not done so some other person might have taken out a patent later on, and then charged Trinity House a royalty for the use thereof. The oil is kept at its proper level by being stored in a separate reservoir inverted, and open only below on the principle of the "inexhaustible" water bottle used sometimes for birds; a valve in the opening prevents the spilling of the oil when the vessel is carried about. Would lamps of this type, said the speaker, be of use for the optical lantern, especially when furnished with a meniscus lens on the plan devised by Mr. Traill Taylor, to throw more of the light upon the lantern condenser proper? Would a reflector, properly curved to throw rays falling upon it back to nearly the centre of the flame, be of more advantage than usual in the optical lantern? It seemed to him that experiment only could solve these points. He illustrated his remarks by diagrams upon the black board.

Mr. W. E. DEBENHAM thought the brass rims conducting the air to the flame would also warm that air.

Mr. HARRISON doubted it; the draught was so swift, that Sir James Douglass said that it performed the useful function of keeping the glass chimney clean for a very long time.

Mr. T. E. FRESHWATER said that the level of the paraffin in the present four-wick optical lantern lamps does not alter much.

Mr. DEBENHAM doubted if a reflector behind the light would be much good for picture projection, but it was good for illumination of other kinds.

Mr. A. HALDON stated that in many of the search lights of the service, reflectors and refractors of the same focus are used together.

Mr. FRESHWATER presented a map which was issued by the Royal Geographical Society on March 25, giving the latest and most accurate information about the Caucasus and the route taken by the late Mr. Donkin. He said that at the time of the loss of Mr. Donkin, a gentleman was travelling in the neighbourhood with photographic apparatus, and started in search of him, tracking the footsteps of the party through the snow, until he came to a glacier where the ground was so rough that he could not cross it, to take up the trail on the other side. In a portion of Mr. Donkin's baggage photographic items were found, including some exposed roller slide negatives, which were brought to England and developed; some of the exposures had been spoilt by subsequent access of light, and some of the negatives obtained were spotted; others produced excellent pictures. His diary, made up to the time of starting on the fatal ascent, was also found. It is supposed that the explorers were destroyed by rolling or falling stones, the dangers on the southern slopes of the Caucasus not being chiefly from snow avalanches; the conditions are not the same as in the Alps. Mr. Freshwater concluded by saying that all the highest peaks in the Caucasus had been first climbed by Englishmen.

Mr. DEBENHAM remarked that of late photography had been largely used for determining the height of mountains from below; a fresh field had been opened in that direction; Dr. Eder had published the details of the experiments.

Mr. HARRISON said that he had suggested to Sir James Douglass that photography would register the height and appearance of waves breaking over light-houses better than the present painstaking drawings, and that should it be necessary to point the camera considerably upwards or downwards in the operation, the distortion thereby produced in the negative could be corrected by optical methods in the copying.

Mr. F. KELLOWS stated that for some time they have been measuring the height of clouds by photography at Kew Observatory.

SHAFTESBURY PHOTOGRAPHIC SOCIAL.

MARCH 29.—Mr. Stuart in the chair.

After songs, music, and recitations, the SECRETARY read a summary of the Club's doings during the last six months, the cash balance proving very encouraging.

The first outing of the Club for this season will be to Epping Forest.

LEICESTER AND LEICESTERSHIRE PHOTOGRAPHIC SOCIETY.

MARCH 27.—Mr. George Bankart (President) in the chair.

Mr. J. B. COOK delivered a lecture entitled *Through Australia and New Zealand*, illustrated with upwards of forty lantern slides reproduced from negatives taken by him *en route*. Mr. Cook's personal experiences and descriptions of the various slides as they appeared on the screen were full of interest and maintained the attention of the audience until the close.

Afterwards the slides which obtained the silver and bronze medals of the Society at the late competition were passed through the lantern and the proceedings brought to a close.

NOTTINGHAMSHIRE AMATEUR PHOTOGRAPHIC ASSOCIATION.

APRIL 1.—The President (Mr. Henry Blandy, L.D.S. Edin.) in the chair.

The minutes having been read, Mr. S. BOURNE read a paper on *Hydroquinone as a Developer*. Mr. Bourne said when, at the Secretary's request, he promised to give a paper on hydroquinone as a developer, he hoped to have been in a better position to deal with the subject than he found himself, as his engagements and the unsuitability of the weather for outdoor photography had left him little opportunity for making experiments with this last addition to our developing agents. The lecturer then gave his experiences with this developer, giving formulae, exposures, &c., exhibiting negatives, transparencies, and prints, fifty magnificent lantern slides being thrown on the screen.

BRISTOL AND WEST OF ENGLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

MARCH 20.—Colonel Playfair in the chair.

Colonel SENIOR delivered a lecture on one of his trips to India, illustrated with lantern slides, taken by himself, of some of the fair and stately palaces and shrines with which that wonderful land is overspread. The lecture took the form of progressive stages, from the large cities in the hot and thickly populated plains to the exquisite scenery of the hill stations, and, further still, to the bleak snows of the Himalayas. The slides illustrating the great temples of Lucknow, Benares, Agra—an index of the laborious patience and great ability of the lecturer—were well received, and the exquisite details of the inlaid and pierced walls calling forth much praise. Colonel Senior showed many views deserving of special comment, from which we would single out, from its remarkable character, a view in the vast, dark, cavern-like interior of that greatest of mausoleums—the Taj Mahal. This view, showing the rich screen fronting the founder's tomb, was taken by him in the days of wet collodion plates by the aid of 5*l.* worth of magnesium wire, which had to be kept burning for a great length of time, as its light was lost in the profound gloom. Another view, showing the interior of a zenana, with a zenana lady attended by two English missionary ladies, was very curious. The opportunity for taking this subject, which possibly has occurred to no one before Colonel Senior, came about through the wish of the noble lord of the zenana to possess a picture of his wife.

Messrs. M. Lavington, H. A. Hutchinson, and J. W. Evens were elected members.

At the next meeting, April 17, Dr. H. Brown will read a paper entitled *The Eye considered as a Camera*.

BATH PHOTOGRAPHIC SOCIETY.

MARCH 27.—Mr. William Pumphrey (President) in the chair.

The CHAIRMAN announced that the first outdoor meeting would take place on Thursday, April 25, Farleigh Castle being the destination.

Mr. A. G. BRISTOW exhibited a shutter he had made to work in the diaphragm slot. The action was that of opening from and closing towards the centre.

Mr. W. M. ASHMAN thought that the provision for opening and closing an exposing shutter in the centre of the diaphragm plate of a rectilinear lens was correct in principle as well as very convenient in practice.

Captain HARRISON drew attention to Sands & Hunter's shutter, which fulfilled these conditions, and was readily adjustable for slow or rapid exposures. He next alluded to the steadiness of the Ashford tripod, especially when used on board ship, and explained to the meeting how, by the use of a view finder to his camera, a fixed focus at seventy yards, and placing one leg of the tripod behind the camera instead of in front, he was able to steer for a wave cloud or other passing object, and so secure any desired subject.

Mr. WALTER PITT exhibited some large prints of mechanical drawings made by means of the salts of iron. This process is largely practised by his firm, and the results were of great excellence.

Mr. GEORGE F. POWELL drew attention to silver prints of the same subject, from two different negatives, one having received a brief exposure in sunlight and the other two hours in moonlight. He thought more attention might be given to photographing landscape in moonlight.

Mr. Ernest Pitman passed round some photographs of snow scenes, 15×12, which he had enlarged from small negatives taken in the locality.

The room was then darkened, and a series of about sixty transparencies of well-known places in the Highlands of Scotland were exhibited by Mr. John Dugdale. These were by the wet collodion process and coloured. The lecture, explanatory of each slide, was read by Mr. Sutton.

At the close about thirty transparencies were exhibited and explained by Captain HARRISON, which were developed with hydroquinone.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

MARCH 28.—The President (Mr. A. W. Beer) in the chair.

The following were elected members of the Association:—Miss Rose Collier, Rev. C. Contenay, Messrs. F. Anyon, Holbrook Gaskell, jun., Henry J. Houghton, Robert Jardine, W. O. Pearson, George B. Prescott, and R. Richardson.

The HON. SECRETARY read letters from Messrs. H. R. Atkins, J. Stanley Riley, and the Hon. Secretary of the Chester Society of Natural Science, offering the use of their dark room to members of the Liverpool Association; and from the Treasurer of the Boston Camera Club, announcing that the set of slides, *Illustrated Boston*, had been dispatched, and stating terms of the trust on which they were to be held.

The PRESIDENT announced that the first excursion of the season would take place on Easter Monday to Ludlow, and that a full card of excursion arrangements was being printed, and would shortly be distributed. He then gave a short account of his visit to the Camera Club Conference, describing the meetings as being very interesting and successful. He also mentioned that Mr. Walker Hughes had been appointed Assistant Hon. Secretary.

The question of supplying refreshments in the Club-room then came before the meeting. After some discussion a resolution was passed that the House Committee be requested to arrange for the supply, on ordinary occasions and within reasonable hours, of simple non-intoxicating refreshments, such as tea and coffee.

Mr. A. G. HARRISON DEARLE then gave his reading on *English River Scenery*, illustrated with a number of slides by York and others. He took his audience along the Thames from its source to London Bridge; then, in succession, visited the River Falls at Truro, Dart Lyn, Avon (Bristol), Avon (Warwick), Derwent, Dove, Nidd, Ure, Brathay, Yare, and Wye, concluding with some views taken by a picnic basket camera, introduced by himself and Mr. Ashcroft.

Mr. Paul Lange followed by showing a set of two hundred slides sent by the Birmingham Society, as the *Illustrated Boston*, which had been announced, had

not arrived as was expected. They were largely of the neighbourhood of Birmingham and Warwickshire, and proved very interesting, although the large number to be got through permitted only a hurried view.

The President announced that an extra meeting would be held on Thursday, April 4, at which *Illustrated Boston* would be exhibited, at seven p.m.

At the close of the ordinary business the meeting was made a special one, as announced by the circular, to consider the question of raising the entrance fee. A resolution was carried by a large majority that all candidates nominated after April 15, the latest date for election at the April meeting, should pay an entrance fee of 21s., instead of 10s. 6d.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

MARCH 28.—Mr. B. Karleese (Vice-President) in the chair.

Messrs. H. S. Gent, C. F. King, J. C. Newry, F. P. Osborne, J. B. Stone, J. P. W. Shakespeare, and T. Taylor, were elected members.

The Hon. SECRETARY read a letter from Mr. J. B. Stone, J.P., suggesting a meeting of the Vesey Club and the Birmingham Photographic Society to promote the interests of advanced and historical photography. This was referred to the Council. Also a letter from Mr. F. Hoskins offering prizes for the best enlargement, 12 x 10, of an instantaneous picture of moving objects taken with the camera held in the hand.

Prizes were also offered by the Lantern Committee for the best six slides illustrating the city of Birmingham, and by Mr. J. H. Pickard for the best three plates to be taken on the Dove Dale excursion.

Mr. WALTER GRIFFITHS then gave a paper on *Various Printing Processes*. During the discussion which followed, Mr. E. C. MIDDLETON said that Aristotype paper was practically the same as Oberetter paper. He asked if any one present knew how the blue process paper could be made to keep; he had known of some that would keep two years.

Mr. HAROLD BAKER mentioned the continuing action of carbon prints after exposure; they would go on printing even in the dark. The best plan was to place them in a calcium tube after exposure if required to keep them for development.

Mr. MIDDLETON: A warm, damp atmosphere is conducive to the continuing action. There is a peculiar action of this carbon tissue. If an exposed carbon print is pressed against an unexposed strip of carbon tissue an image will be formed as if it were placed under a negative, and by the continuing action a picture can be obtained. The calotype process is a very rapid process; a printer can begin to pull off prints in twenty minutes from receiving the negative, and can get them at the rate of 500 prints a day. Line drawings can be made by printing with blue process; then going over the outlines, &c., with pen and ink, and washing off the blue print, leaving in appearance a line drawing.

Correspondence.

Correspondents should never write on both sides of the paper.

PERMANENT HYDROQUINONE.

To the Editor.

SIR.—Mr. Levy, in his elementary analysis (see page 163 of THE BRITISH JOURNAL OF PHOTOGRAPHY), ignited two different preparations, namely, the ordinary white, and the so-called "permanent hydroquinone," and has found that the white contained 57.3 per cent. of carbon, and 6.19 per cent. of hydrogen; the permanent, 47.75 per cent. carbon, and 6.74 per cent. hydrogen; whilst, theoretically, pure hydroquinone— $C_6H_4O_2$ —requires 65.45, and 5.45 per cent. respectively.

So striking a result should have induced a conscientious experimentalist to repeat the trials, in order to see if the second test would give identical figures, though Mr. Levy has apparently not thought this necessary, but hit upon another very practical (?) idea. He assumes, without further reflection, that his two tests are correct, and ascribes the difference between the theoretical quantities of carbon and hydrogen and those found to the presence of water of crystallisation in the two samples examined. According to his theory the white crystals contain 12.8, and the permanent 27.27 per cent. of water.

Now, even those possessing a merely superficial knowledge of analytical chemistry are aware that water, whether only mechanically combined or as water of crystallisation, may be determined quantitatively with the greatest ease. As already stated, the ordinary white hydroquinone was supposed by Mr. Levy to contain 12.8 per cent. of water, but for a compound of the formula $C_6H_4O_2 + H_2O$ —i.e., containing one molecule of water—the proportion would be 14.06 per cent. As hydroquinone has, however, been examined by a large number of chemists, including the celebrated Woehler, we must, *a priori*, reject the possibility that all of them can have overlooked the presence of one molecule of water.

With "permanent" hydroquinone the case might possibly be slightly different. This had so far only been alleged to contain sulphur only, or rather sulphurous acid, and it was possible water might also be present in the crystals; so to test the accuracy of Mr. Levy's allegation, it was necessary to repeat his analysis. This I have done with results very different from his. The sample operated upon exhibited the same properties as those mentioned by Mr. Levy, and melted at 171°–172°.

The hydroquinone reduced to fine powder was first dried for several hours over sulphuric acid in the exsiccator until the weight was con-

stant, the loss, however, being extremely minute. It was then heated for some time in an air-bath of 110° to 115° Celsius, which produced a decrease in weight of .5 per cent., attributable partly to some mechanically combined moisture, but partly also to the sulphurous acid contained by the permanent hydroquinone, which escapes to some extent at that temperature. The substance thus dried was ignited with chromate of lead in two separate tests.

I. 0.2105 grs. gave 0.502 grs. carbonic acid, and 0.1107 grs. water.
II. 0.2140 " 0.511 " " 0.1110 "

Or compared with the theoretical constituents of pure hydroquinone—

	Calculated for $C_6H_4O_2$	I.	II.
Carbon	65.45	65.01	65.12
Hydrogen	5.45	5.81	5.76

From this it follows that permanent hydroquinone may be said to be, practically speaking, chemically pure.

I am of opinion that the small quantity of sulphurous acid to which the preparation owes its permanency is not chemically but only mechanically combined.—I am, yours, &c.,

DR. MARTIN FREUND,
Professor at the University of Berlin.

VALUATION OF HYDROQUINONE.

To the Editor.

SIR.—There appears to be a slight mistake with reference to the question of water of crystallisation presumed to be present in commercial hydroquinone. I have simply pointed out that this hypothesis gives results closely agreeing with the actual constitution of the pure compound. In point of fact, I have employed very similar methods to those used by Dr. Langer, and have not been able to detect any water. As Mr. Bolton puts it, the discrepancy in the carbon must be looked for elsewhere.

I have not been able for the past week or so to continue my investigation, but hope to be able soon to find some explanation of the anomalous results given by the combustion. That the figures yielded by the elementary analysis be correct, I believe there can be no doubt, as a number of combustions give identical results.

The analysis of pyrogallous acid published last week will show how close the figures of two trials are one to another.

Dr. Langer may rest assured that every precaution was taken to ensure accuracy.

This terminates all I shall have to say for the present on this subject. Now as to Mr. Smith's letter.

I do not think it is usual for scientific men to indulge in insinuations such as those embodied in the last sentence of the first paragraph of Mr. Smith's letter. If I read him rightly, he infers that I am not conscientious in recording the results afforded by the analysis. I do not think that the remarks referring to the number of decimal places are of a character to justify their being in a letter emanating from a gentleman, who, no doubt, is an experienced man, but who has not been able to deny himself the pleasure of a mild joke at the expense of a brother chemist who has not the good fortune of meeting with his approval.—I am, yours, &c.,

ADOLPH M. LEVY, C.E.

37, Bassett-road, W., April 2, 1889.

Exchange Column.

* No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

Will exchange a new Optimus nickel-plated chair head-rest for a polished steel plate, 11 x 14.—Address, R. W. SIMMONS, Galway.

Will exchange Rosa No. 11, 12 x 15 symmetrical, for No. 8, 10 x 8 symmetrical. Difference adjusted.—Address, J. H., 10, Victoria-road, Penrith.

Two sets of lantern slides or slides coloured to value in exchange for an oxygen gas bag in good condition.—Address, THOMAS GILLIVER, Branawick-street, Swansea.

Will exchange threefold tripod, half-plate, Lancaster's folding ruby lamp, Burton's book on *Printing Processes*, Marion's Guide, and thirty-six numbers of the *Photographic News* from June 1, 1888, for a good half-plate burnisher.—Address, W. H. SIMPSON, c/o Mrs. Watson, Wenden-street, Wakefield.

RECEIVED.—*Republique de Uruguay; Un Voyage à Paris*; Jarrold's *Norwich and Eastern Counties Handbook*; Asiatic Society of Bengal; and The Address of Mr. William Crooks, F.R.S., at the annual meeting of the Chemical Society.

MR. E. KELLEY, of Old Town-street, Plymouth, from whom we had a call the other day, informs us that carbon opals are in much favour in his part of the world. He left with us some specimens of his work (he prints for the profession), and they are really charming.

Answers to Correspondents.

••• Communications relating to Advertisements and general business affairs must be addressed to "H. GREENWOOD & Co.," 2, York-street, Covent Garden, London, W.C.

All matters for the text portion of this JOURNAL, including queries for "Answers" and "Exchanges," must be addressed to "THE EDITOR," 2, York-street, Covent Garden, London, W.C. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.

PHOTOGRAPHS REGISTERED:—

AMBROSE BARR, Ayr, N.B.—Two photographs of the meet of Lord Eglinton's hounds at Auchan Cruise. One photograph of Lord Eglinton's hounds with master and whip.

VOLVO.—On the first Friday in each year.

INQUIRER.—We are making inquiry respecting the book.

PAPER.—Yes, the engraving can be photographed and a good lantern slide made from the negative.

T. P.—There is a decided nucleus in the centre of the white spots. See leaderette in present number.

J. G.—Your mistake consists in the employment of bicarbonate (or baking) soda instead of the mono-carbonate (or washing) soda.

T. B.—Either of the lenses will give the distance correctly defined. The landscape lens is the better of the two for landscapes.

A. FOSTER.—You will find particulars for an emulsion for opal plates in last week's "Answers to Correspondents," under the name of "Captain Barlow."

L. MARTIN.—If you cannot obtain dark tones in a transparency with the ferrous-oxalate developer try the pyro-sulphite or the hydroquinone developer.

CARDON TISSUE.—The following are particulars of the sensitising solution you require:—Bichromate of potash, one ounce; water, twenty ounces; liquid ammonia, six drops.

H. SPINK.—There are single lenses now made which work with an aperture of $f/8$. For a head two and a half inches, the focus of the lens should be from sixteen to twenty inches.

J. D. WEBSTER.—Much better to have the illustrations made by a collotype process, such as that by which the Convention groups in this JOURNAL of the past three years have been produced.

LCMEN.—There is no restriction in photographing either in Mexico, Texas, or any part of the United States of America. We do not vouch for non-interference by Indians in some quarters.

W. T. L.—The lighting of your studio could be improved by increasing the side light as well as the sky light, especially the former. We advise you to make both lights the same, namely, to the full extent you propose for the roof.

CHEMICALS writes: "I am fitting up a dark room; would you advise the ruby light or lamp to be in a box fastened in the wall or a gas-jet with flexible tale, so as to move it in any position as required?"—Reply: We prefer the latter plan.

A. G. FIELD would like if any reader would refer him to any articles that may have been published relative to the transforming an ordinary camera into a detective. He believes that he has seen such an article either in ALMANAC or JOURNAL.

A. A.—We have proved by the experience of many years that a silver image bleached by bichloride of mercury possesses the property of permanence in a singular degree; but it must be kept dry and free from sulphuretted hydrogen and like gases.

A. Z.—Several articles on the Woodbury process appeared in our volume for 1883 and in 1884. In the latter it is found under the heading, *The Stannotype Process*. Information may also be obtained in the last edition of Hardwich's *Manual of Photographic Chemistry*.

T. C. A.—As you have never tried retouching a negative, it is hardly possible that you will be able to make a "good job" of the negative about which you wrote. Better have it finished by a professional. You somewhat remind us of the man who, on being asked if he played the violin, said he did not know, as he had never tried.

JAMES SIMS.—The mealiness of your prints is not due to the toning bath. Possibly the silver bath is too weak; or, maybe, the negatives are at fault. If deep purple or black tones are desired, they can only be obtained from very vigorous negatives, and then the paper must be strongly salted, and correspondingly strongly sensitised.

WATER.—1. Rain water will do quite well for making silver solutions, provided it be pure; but rain water caught in the neighbourhood of large towns or from roofs of houses is, as a rule, far worse than ordinary tap water for photographic purposes.—2. The mere fact of the water being "hard" will not unfit it for washing prints and negatives.

R. S. W.—The alcohol may be strengthened to a sufficient degree by drying some carbonate of potash over a heated plate of iron (a shovel will do) and adding this. Shake up the bottle well and allow the surplus carbonate to subside, when a layer of aqueous solution will be found above this deposit. The rationale of this is that the water has an affinity for the potash, but the alcohol has not.

J. ROBERTS.—Having made the transparency on a thin collodion, float it from off the glass by placing it in water acidulated with sulphuric acid. Then float it on the surface of the wood, on which it must then be allowed to dry. But precautions must be taken not to allow water to be absorbed by the wood, else it may interfere with its suitability for engraving.

ANXIOUS writes: "Can I make dry plates for my own use cheaper than I can buy them? if so, kindly give the full particulars, as I am quite ignorant of the *modus operandi*: in fact, I have only just taken up photography."—Space in this column will not admit of such particulars as would be required in your case. We recommend you to purchase plates ready made; any dealer will supply you.

E. ANSCOMBE.—Paper prepared in the way you mention would necessarily be very slow. Possibly your failure has arisen from under exposure. Try daylight instead of artificial. Your best plan would be to begin with one or other of the commercial bromide papers; they are very sensitive and well adapted for artificial light. When you are proficient with these papers, you might then begin preparing your own paper.

TRIPEAL MONOPTICON.—If you require to include a wide angle you cannot do so with a rapid lens. Therefore, we advise you to have two lenses—one of the "rapid" and one of the "wide angle" type. The former may be from five to six inches, and the latter from three to three and half inches focus. It is against our rule to recommend any particular maker's goods. All the makers mentioned on your list are in good repute.

E. W. M. writes: "I shall be obliged if you will inform me whether I am free to photograph in Normandy and Brittany without being regarded as a spy by the authorities; also whether these provinces contain much that is of antiquarian as well as photographic interest. If one is debarred from photographing in any part of France, will you kindly name two or three places where I may find food for the camera as well as something to gratify an antiquarian taste, if possible combining the two?"—Will some reader kindly reply?

R. WATKINS sends us a cabinet portrait of a lady ascending a staircase, and says, "What do you think of it?"—The chemical part of the picture is very good, with the exception that there are several scratches on the surface of the print; this, however, can be obviated in future by cleaning the burnisher. Respecting the artistic portion, you appear to have taken great pains in the arrangement of the dress of the sitter, but, unfortunately, it detracts from the beauty of the picture. Had the figure been standing on level ground everything would have been correct, but, seeing the figure is represented as ascending a stair, the drapery should have been so arranged that the idea of motion is conveyed to the eye. Had the lady ascended the two steps and been thus photographed without the "arranging" you speak of, the effect would have been more natural and more artistic. Study some photographs by high-class artists and you will acquire better ideas of the art of posing.

CAMERA CLUB.—On Thursday, April 11, Mr. Valentine Blanchard will give a demonstration of his platinum block printing process.

LIVERPOOL AMATEUR PHOTOGRAPHIC CLUB.—The last day of nomination of new members under the old fee is April 15, 1889; afterwards the entrance fee will be 21s.

NORTH MIDDLESEX PHOTOGRAPHIC CLUB.—On April 8 Mr. Clifton will give a demonstration on Carbutt's films at the Iron Room, Stroud Green, to commence at a quarter past eight. Visitors are especially invited to attend.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—Ordinary meeting, Tuesday, April 9, at eight p.m., at the Gallery, 5A, Pall Mall East. Mr. Friesse Greene will read a paper—*Some Effects probably due to Phosphorescence, Electricity, and Colour Sensitiveness*.

MANCHESTER PHOTOGRAPHIC SOCIETY.—The last meeting of the lantern section of this Society was held in the large room of the Manchester Athenaeum, on Wednesday, March 27, 1889. The evening was entirely devoted to photographs by the Hon. Secretary (Mr. W. I. Chadwick). The first series shown on the screen were views in Canada and the United States of America. Mr. Chadwick, who described his pictures as well as manipulating the lantern, said it would be impossible to exhibit in one evening all the photographs he had taken on a tour of fifteen thousand miles in Canada and the United States. He had, therefore, selected from his stock and arranged the present series, as forming a short pleasure trip for those who felt inclined for a spin across the Atlantic; the series consisted of about two hundred pictures. The second series consisted of about a hundred and thirty photographs of the Manchester Jubilee Exhibition, 1887, taken by himself for the Executive Committee. These came as a surprise to the audience, who showed their appreciation by frequent applause. It concluded by an exhibition of the Fairy Fountain in all its fairy-like beauty, magnificence, and change of colour. The effect was produced by an ingenious contrivance of the exhibitor, and excited the audience to enthusiasm.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1510. VOL. XXXVI.—APRIL 12, 1889.

[The following appeared in our issue of last week.]

REDUCTION IN PRICE OF "THE BRITISH JOURNAL OF PHOTOGRAPHY."

IN view of the unprecedented success of THE BRITISH JOURNAL OF PHOTOGRAPHY since its foundation, thirty-five years ago, the proprietors believe the time has arrived for increased effort to meet the ever-growing popularity of the JOURNAL, and that this purpose will be attained most effectively, both for readers and advertisers, by the reduction of the price of the JOURNAL from 3d. to 2d.

This important reduction in price will doubtless still further increase the influence of the JOURNAL, and largely augment its already extensive circulation at home and abroad.

Subscribers who have already paid their subscriptions on the old scale will have the reduction placed to their credit or remitted, as they may desire, by the Publishers.

The Editor takes this opportunity of assuring the readers of the JOURNAL that the reduction of price above referred to will not in any way modify the general conduct and efficiency of the JOURNAL, which will be carried on, if possible, with increased energy in every branch of photographic research. The services of specialists in every department are secured as heretofore. This includes patent law as applied to photographic inventions; chemistry and optics; while in the departments of practical and theoretical photography, in all its branches, nothing will be left undone to ensure the continuation of the high position the JOURNAL has always maintained.

A commodious and well-appointed dark room has just been fitted up at the editorial and publishing offices, which will be at the service of any one who desires a suitable place for changing dry plates or for making experimental or tentative trials of developers. Friends passing through London to or from the provinces, India, the Continent, America, and elsewhere, will find this a source of great convenience.

The publishers desire us to announce that in accordance with the reduction in price, the subscription will be as follows:

ANNUAL SUBSCRIPTION.

(Post free, payable in advance.)

	s.	d.
United Kingdom and Channel Isles ...	10	10
France, Belgium, United States, Canada, Australia, New Zealand, Africa, Newfoundland, Germany, Portugal, Spain, Italy, Egypt, &c. ...	13	0
India, China, Japan, &c. ...	15	2

It also may be obtained from all booksellers, photographic dealers, and railway bookstalls, price 2d. Special terms to Photographic Societies.

APPLIANCES FOR FACILITATING FOCUSING.

THE Exhibition at present open in the Crystal Palace affords us an opportunity of noticing peculiarities in the construction of apparatus and of special features which form idiosyncrasies of makers of various nationalities. One of these forms the topic of the present brief article.

How to focus a large camera? That is not the sole question, but a portion of it, which may be expanded to this—By what means can the ordinary sliding body of a large camera be made subservient to quick adjustment coupled with the most delicate regulation of focus?

This, we think, can be best effected by an ingenious lever adjustment invented by M. Flammang, of the American Optical Company, and which, although our then American correspondent described and spoke highly of it soon after its introduction, is so excellent that we have every excuse for here giving a full account of it, especially as—if we correctly apprehend the matter—it is not secured by patent, but is open to all. And it is with much satisfaction we observe that, at the Crystal Palace Show, at least one eminent English firm manufacture some of their large studio cameras on the principle and with the appendage alluded to, and which we recommend for general adoption by all who make large cameras.

Premising that the quick extension of the body is made to take place by means of two A-shaped laths of rails, one at each side, over which the body slides smoothly owing to little wheels being "let in" having grooves on the edges to correspond with the tops of the rails, the rough adjustment having been effected by this. We now direct attention to the lever fine adjustment, as shown in the diagram on next page, and in which *a* is a small plate screwed to the back of the camera.

The circle *d* represents an ordinary milled-headed screw, which travels through a slot in the tailboard of the camera, and which is loosened when a quick adjustment is being made. It is then pinched and clamps *e* to the baseboard.

At one end of *e* is an eccentrically placed flat, circular plate, *e*, which forms part of the same casting as *e*, but is raised up a little higher. Pivoted by means of a strong pin near the margin of *e* is a lever, *f*, by moving the handle of which backwards or forwards (*e* being now supposed to be clamped) the end of the camera, *a*, is acted upon through the intermediation of the link *b*, and an extremely smooth adjustment made—not

only with great delicacy, but also with rapidity. When the final focussing has been adjusted by means of the fingers of the right hand, which grasp the handle f^1 , the point of the thumb

is pressed with a rotary motion against the milled head of a screw, g , by which it is firmly clamped with the plate underneath, and everything thus made rigid. For all large studio cameras this system of focussing is to be most strongly recommended.

For cameras of the hand, or detective class, the same idea may be usefully employed, but in a greatly simplified form. In one which we had constructed, the lever, f , consists of a straight strip of brass, one end of which works on a screw, as a fulcrum, placed in the side of the camera; the link, b , being affixed to the centre of the lever by a loose rivet, and the end, f^1 , travelling over a scale graduated to represent the various distances of objects from the camera. A considerable movement of this outer index end represents only a very small motion of the adjusting portion of the camera.

ILLUSTRATIVE PHOTOGRAPHY.

MANY who are even old and experienced photographers have, apparently, but little idea of the extent to which photography is employed for illustrative purposes. All, of course, are familiar with such processes as photogravure, Woodburytype, photo-lithography, colotype, and analogous processes, but they do not seem to be aware that many of the illustrations in the better class of periodicals and books, which pass as woodcuts, are perfectly innocent of the wood-engraver's art. These blocks are in reality produced by photochemical means. We are not here alluding to the half-tone "process" blocks often met with, and which a photographer would at once recognise, but to line subjects, such as are usually looked upon as being wood engravings.

It is not our intention in this article to enter into the manipulatory details of the different processes by which the blocks themselves are made, but rather to indicate how photography is being utilised in this particular direction. This we do in the hope that some of our readers may possibly see some fresh channel, in their own immediate sphere, in which the art-science may be applied that may not have occurred to them before.

Let us consider how a typographic block—say, for example, for such a work as the *Illustrated London News*, the *Graphic*, or *Punch*—is produced. Indeed, the last-named periodical was ~~one of~~ the first, we believe, of the better-class journals to utilise phototype blocks. In the first place the artist makes a drawing

of the subject in line, generally on a somewhat larger scale than that required for the block. The drawing may be made in pencil or crayon, but pen-and-ink is preferable, particularly when the drawing is on a small scale. The lines are always made bold and well defined. From this drawing a negative is taken of the size desired, and from this the block is made by one or other of the well-known zinc etching methods. A little consideration will show that this way of producing illustrations possesses many advantages over wood engraving. For example, the original drawing and touch of the artist are strictly preserved, as they have not to be transcribed by a draughtsman or by the engraver. If the drawing be finely and cleanly executed—which, by the way, is seldom the case—the block will be quite as good as a very high-class woodcut. The work is also more expeditiously and cheaply done. A block which would take many days to engrave may be produced by the photochemical process and made ready for the press in a very few hours.

When illustrations are taken from photographs, it is very common to make a sketch, in line, from the picture, and then proceed in the way just indicated. Frequently in the sketch considerable alterations are made from the original—figures introduced in the case of landscapes, or the dress metamorphosed in the case of portraits—occasionally, we regret to say, not with the view of improving the picture so much as evading the copyright in it. Sometimes, however, a tracing is made from the photograph, of course in line, and this is copied. Some of the large portraits used as "posters" are obtained in this way, from an enlargement on bromide paper made from the original negative.

There is another, and perhaps a neater plan than tracing, of transforming a photograph into a line picture, though it is less frequently practiced, probably because it is less generally known. It consists in making the line drawing, or tracing, direct on the photograph itself with pen and ink, and, after it is dry, destroying the photographic image, leaving only the drawing lines on a white ground. This is done by immersing the picture in a solution of bichloride of mercury. When working in this way it is scarcely necessary to say that the photograph must not be toned with gold—only fixed in the hypo bath. Enlargements on bromide paper are well adapted for this system of working, as the image is easily bleached with the bichloride of mercury. Of course, working in this way, the picture can be modified just as readily as in the case of a tracing, because after the mercurial treatment no trace of the photograph remains. Furthermore, the drawing being obtained on a large scale, the result, when reduced, is more satisfactory than when the drawing is, in the first instance, made the size of the block required; unless, indeed, the work is more delicately executed than is generally the case.

Before concluding this subject it may be well to refer to a very ingenious method of modifying photographs which is practised at the Ordnance Survey office, which, in the result, becomes very similar to that just described. Here, however, the original image is not destroyed. It is produced in the first instance in a very faint and highly actinic colour, so that its photographic value is about the same as that of the paper upon which it is printed.

It may be explained that all the Ordnance maps are first drawn on a large scale—ten feet to the mile—and, from these originals, reductions to the different scales are made in the camera. Now, it is very clear that if this large scale be reduced to, say, one inch to the mile, the roads, paths,

names of places, and other fine details would be too small to be readily distinguishable. Hence they have to be made proportionally larger in the smaller scales. This is done as follows:—

An impression is taken from the zinc plate of one of the medium scale, in a very pale blue ink. Then this print is gone all over with a ruling pen charged with strong black ink, keeping on the outside of the original lines, so as to make the roads, lanes, &c., wider. The same is done with the other fine details, so as to make them bolder. The names are also put in with large type. When finished—that is the map redrawn, or rather traced—it is copied in the camera to the smaller scales. Although the original image still remains, the pale blue ink in which it is printed has the same actinic value as the paper, hence it does not show in the copy. By this simple means the accuracy of the map is retained, and the finer details are secured on a larger scale.

As the experiment of last year, of withholding medal awards in connexion with the Annual Exhibition of the Photographic Society of Great Britain, is conceived to have had a detrimental effect upon the success of the Exhibition of 1888, it was decided on Tuesday evening last that medals shall be awarded as formerly. In accordance with the recently adopted rules, the election of judges will be made by the members of the Society, instead of by the Council as formerly. Of this, and other details, due notice will hereafter be given.

We spoke last week of a new or modified method of obtaining prints in platinum which was about to be introduced by Mr. Blanchard. Our issue of to-day contains a very important letter from Mr. Lyonel Clark, in which he describes a process for effecting the same end, and the reasoning by which he was led to adopt it. We bespeak for Mr. Clark's communication the careful attention of our readers.

The employment of citric acid in various operations of photography is so general that a ready means of detecting the presence of tartaric acid in any suspected sample will be of value. M. Salzer, in a foreign journal devoted to this class of subjects, describes what appears to be a very simple method, one not involving the use of any chemicals beyond those to be found in any ordinarily furnished photographic laboratory. The method of testing consists simply in adding to a solution of the suspected crystals a drop of solution of yellow chromate of potassium. If the acid be purely citric, the yellow colouration thus produced remains unchanged for some days at ordinary temperatures, even if a few drops of sulphuric acid be added. If, however, tartaric acid be present, the yellow chromate is converted into a violet salt of chromic oxide. M. Salzer states that the presence of so small a quantity as one half per cent. will be shown by this reaction after the liquid has stood for a few hours.

In a work of very considerable value which *Nature* reviews, under the title *The New Traveller's Guide to Scientific Inquiry*, photography holds a position of importance. The work is published with the intention of providing "the numerous German travellers and dwellers in foreign lands with a simple introduction to scientific investigation in the various departments of natural science." Some men of science of the highest standing have contributed to this work, which is really a series of articles upon various subjects, each written by a specialist of eminence. Dr. Gustav Fritsch is the writer upon the microscope and photography. "This latter has, owing to the perfection of the dry plate methods, become so easy of practice that no scientific expedition is completely furnished without a photographic outfit, and it is satisfactory to see its various uses brought prominently forward in a work of this kind," says *Nature*. "Special attention may be called to the mode of recording the topographical features of a country by means

of panoramic photographs taken from properly selected points of view and to its peculiar advantages for the collection of anthropological data

THERE is no doubt that photography deserves all that is here and more, and its value will be still greater when it is customary bring before the public, or even the mass of scientific observers, actual photographic results, and not the engraver's transcripts (more correctly phrased, perhaps, as "translations") of imperfect prints brought out as exquisite and delicate bits of engraving of what some one might think the photograph was like. There are processes, and to spare now, which enable results of considerable value to be printed along with letterpress, while, if some of the collographic processes employed, the results are little inferior to silver prints.

Our friend, Mr. W. K. Burton, has forwarded the first copy of a Japanese photographic journal with which he is connected. The journal is of the size termed Demy 8vo., and to external appearance is got up in the English style; but on opening it a difficulty arises, and it is somewhat doubtful whether the reader has to commence at (what appears to us) the end of the book, or *vice versa*. Another difficulty is whether one has to read upwards, downwards, or sideways. Relative to the matter contained in the journal we rest content that it is all right, seeing such an able writer as Mr. Burton is connected with it. However, for the satisfaction of those who are curious we reproduce a portion of a page of this new journal.

We are pleased to observe that a new photographic society—East Dulwich and Peckham Photographic Society—has been formed. It is intended to hold meetings fortnightly during the winter months and once a month during the summer. We wish the Society every success.

THE cause of the blue colour of the sky often used to be a subject of dispute among scientific men, until Professor Tyndall appeared to have set it at rest by propounding the theory of its being the product of selective reflection of the blue rays of white light by reason of one presence of particles in the air of such minute size as only to be able to reflect rays of short wave length. Professor Hartley has recently propounded a new theory, which really seems to be a more probable one. After raising objections to Tyndall's theory *per se*, he presents his own arguments and the results of experiments to show that the blue colour arises from the action of ozone upon the rays of light. They showed that the results of his examinations of ozonised air proved that it was impossible for rays of light to pass through so little as five miles of air without the rays being coloured sky-blue by the ozone commonly present, and "that the blue of objects viewed on a clear day at greater distances, up to thirty-five or fifty miles, must be almost entirely the blueness of ozone in the air." In his laboratory experiments he observed that the quantity of ozone giving a full sky-blue in a tube only two feet in length is two and a half milligrammes in each square centimetre of sectional area in the tube.

MR. ISAAC ROBERTS, whose wonderful nebulae photographs have lately excited so much interest in the astronomical world, does not confine his gifts to the science to the mere, what we may term

operative part of observational astronomical photography, for we learn that he has lately presented a photographic reflecting telescope to Dunsink Observatory, and, further, completed his generous gift by erecting the instrument at his own cost.

THE above instrument has a mirror, by With, of fifteen inches diameter, a size which will enable a great amount of useful work to be done, but which, so far as size alone is concerned, reads as very insignificant by the side of Mr. Common's new telescope. This is also a reflector (silver on glass), and has the enormous diameter of five feet. The reflector has already been tried, and we believe with perfect satisfaction, photographs of the moon and of nebulae having been taken with the purpose of testing its curves.

It is idle at the present time to speculate how optics or photography will be influenced by these discoveries, but we may be sure that the services of the latter will be in request. Dr. Oliver Lodge writes of these marvellous discoveries: "In 1865 Maxwell stated his theory of light. Before the close of 1888 it is utterly and completely verified. Its full development is only a question of time and labour and skill. The whole domain of optics is now annexed to electricity, which has thus become an imperial science."

ON Wednesday forenoon, and for one or two hours after midday, London was plunged into a darkness of a phenomenal nature. It did not quite partake of the character of a November fog, as the gas lamps could be seen at a distance of many yards. It was simply a midnight darkness, accompanied during a portion of its continuance by a rather heavy fall of rain. The poor metropolitan photographer has evils to contend against of which his more fortunate provincial brother is unaware.

ECHOES.

It is possible to question one of the deductions arrived at by "W.H.D." in his article on *Mercurial Intensification* a fortnight ago. He speaks of the gradually improving character of a series of gelatino-bromide negatives taken during a period extending over six years, and, as I understand him, attributes the result entirely to the increased knowledge of the process and consequent greater skill in development. This may be true to a certain extent, to be sure, but I scarcely think it can be set down as the only reason. Are we to take no count of the improvements in the *manufacture* of the plates? I am pretty certain that at least as much of the progressive improvement is to be traced to the plates rather than the manipulator. Some time since I "rummaged" out a half packet of plates dating from the earlier—not earliest—days of commercial gelatine plates, and exposed them out of curiosity, to see if they had retained their good qualities, they being then about six years old—perhaps a little more or less. Compared with negatives taken upon plates by the same maker at about that distance of time back, they were quite indistinguishable, the same peculiarities, the same good and bad qualities being present in both, though the more modern plates from the same source, while exhibiting similar general characteristics, presented fewer of the bad and more of the good points. Granting I myself had improved in my developing powers, the old plates should have given better results than formerly, since they retained their original properties apparently undeteriorated; but such was not the case.

I cannot help alluding to the disappointment contained in last week's JOURNAL in the publication of the long-expected specification of Dr. Hill Norris's promised "rapid" collodion process. Like all old collodion workers I have a strong feeling in favour of the "old love," not only for the quality of its results, but on account of the comparative independence of plate makers it offers. I was therefore gratified at the announcement made by the veteran at the last Conference, but from the description then given I feared the process would not come up to the ideal of what such a process should be. But I was not prepared for such an "*eclaircissement*." Fancy going

back to preparing your own plates, when each one would occupy at least an hour of time!

A remark made at the last meeting of the London and Provincial Association with respect to the difficulty experienced by dwellers in towns in taking cloud negatives, from having to point the camera up to the sky, may be interpreted too strongly by some of the younger readers. Of course, in the streets of London or any large city the chances of cloud negatives are not plentiful, but even there from the roof of an elevated building the task is not impossible. But half an hour or an hour's ride into the surrounding country, or even suburbs, will afford many opportunities. Once get somewhat clear of the "chimney pots," even elevated ground is not absolutely necessary, though it is an advantage. What is required is a tolerably unbroken horizon, i.e., without any serious irregularities in the shape of individual trees, buildings, or church spires, and a moderately open space in front of the camera. It is surprising at how low an angle the camera may be pointed under such conditions. No further afield than Hampstead Heath, Highgate, Streatham, or even Clapham Common, or round the neighbourhood of the Crystal Palace, any number of spots may be selected from which cloud negatives may be produced when—most important point—there are any clouds worth taking. If the camera can be planted in the upper window or on the roof of a house so much the better, but my pet position in the London neighbourhood would be, if it were attainable, the top gallery of one of the towers at the Crystal Palace; there, I think, the standpoint could scarcely be improved if the outlook were over the ocean; but I am afraid "vested interests" and "monopolies" would stand in the way of even the amateur, for the wonderful and newly developed interest taken by the Palace authorities in photography is closely connected with its money side.

Apropos of Mr. W. K. Burton's method of eliminating pyro from prints by alternate washings in hot and cold water, I may just mention a plan I saw at work in a large professional establishment some years ago, when the prints were required to be finished quickly. I have myself adopted the same plan with manifest advantage in the case of gelatine negatives. It consists simply in giving the prints or negatives a moderately good washing in the ordinary way and then drying. This is followed by another immersion in fresh water for a few minutes, when any trace of hypo remaining in the dry film is rapidly and apparently completely removed. It presents but little trouble when a few prints are required to be mounted quickly.

JUNUS.

CRYSTAL PALACE INTERNATIONAL PHOTOGRAPHIC EXHIBITION.—IV.

MAINTAINING the position of having an exceedingly large, varied, and attractive display at the last Crystal Palace Exhibition, Messrs. Marion & Co. this year make a show in no wise inferior to it in any respect, but still more attractive, inasmuch as it contains the novelties of the year—at any rate, such novelties as have been inaugurated by themselves, or by the increasingly large fraternity of inventors for whom they are agents, or whose goods they handle. But the fact of a thing being new and good at a previous period must not be held as conceding that it is not still excellent. Nevertheless, bearing in mind that some of their exhibits have already been described with considerable fulness in these pages, we shall, at present, give a first place in our description to those of the past twelve months.

First of all, we notice that in their large Middlemiss Studio Cameras (which are here in every size, from half-plate to 15×12) they have adopted a system of lever fine adjustment for focussing, of which we have previously had occasion to speak in terms of the highest commendation when describing the focussing system adopted in some of the large American portrait cameras, and of which we give a detailed account in another page.

Passing over a very great variety of other cameras, we notice their "Dolce," specially intended for taking children's portraits. This has a false front that fits before a studio camera, and within it is a shutter and a bird. By pressing a pneumatic ball, the bird springs out and gives a cuckoo's cry, and, when the child's attention is thus secured, the turning of a tap opens the shutter and the exposure is effected.

Among cameras of the hand or detective class, Messrs. Marion have several possessing different characteristics. Of these, the McKellen

Detective and Krugener's Book Camera have already (pages 693-4 of our last volume) been fully described. The plates in the latter having been so small, $1\frac{1}{2}$ inch square, we are glad to observe that a new edition of the book camera is now prepared, in which plates $3\frac{1}{2}$ inches are used; this will expand its sphere of usefulness. Academy and Parcel Cameras also range in this class. The display of Voigtlander lenses (for which Marion & Co. are sole agents) is exceptionally large, and includes those of every form made by this manufacturer; stands for studio and field, shutters, chemical cabinets, sets, and, in short, every requirement for the photographer. Their "vignetting serrator" is an ingenious little instrument in form of a

Fig. 12.

pair of pliers, for serrating the interior edge of a vignetting mark. This is quite new.

The magnesium flash light of this firm is shown in the following

Fig. 13.

diagrams, one of which represents the lantern erected on a stand. It is faced with paper so as to give a soft light, a person being torn

Fig. 14.

away in the cut to show the position of the lamp, of which a larger representation is here given, A being the circular flame through the

centre of which the magnesium powder, fed in at the hopper, B, is projected.

David Noakes & Son have a large display of lantern appliances, similar to that of last year. Among their novelties is a patent dis-

Fig. 15.

solver for triple lanterns, which is worked by means of a coupler and handle, as shown in the figure.

The name *Invicta* is a trade term applied to their cameras, lenses, instantaneous and time shutters, enlarging apparatus, &c., all of which are well represented in their exhibit.

Jonathan Fallowfield's exhibit includes cameras of every conceivable style, from those of a large size down to a small one of a detective character, mounts, sunk and plain, complete photographic outfits, tripod and table stands, lenses, shutters, trays, chemicals, rolling presses, sinks, backgrounds, and dark room lamps, fitted for either oil or gas.

The display of this old and well-known caterer for the photographic public is of a highly representative character, and proves quite educational to those who elect to study its several components.

Negretti & Zambra have a display of dry plates, lenses, paper, and prints. These are such as keep up the well-earned reputation of this old-established firm.

The Blair "Compact" Reversible-back Camera, an American production, is exhibited by Samuel Fry & Co., Limited. It claims to possess all the desirable facilities, combining lightness with rigidity. It is provided with a patent actuated focussing screen,

Fig. 16.

Fig. 17.

protected with a mahogany sliding piece, so that when folded it may be carried without a case with little fear of breakage of the ground glass. It will be observed from the cut that it occupies little space when folded.

These dark slides are fitted with shutters similar to those introduced

some time ago by the Scovill Manufacturing Company, of New York. No hinges are employed. In order to fill the holder the shutter is drawn out, and the plate is then dropped into the slide at the front and held in position by a spring and blocks. The shutter, which is entirely withdrawn from the holder during exposure, has one of its sides roughened, on which may be written all particulars relative to

Fig. 18.

the exposure of any negative, as is shown in the above cut. Chemicals, grooved boxes, paper, dry plates, &c., form a large element in the exhibit of this firm.

A new patent detective camera is shown among the exhibits of W. W. Rouch & Co. It is made in two sizes ($3\frac{1}{4} \times 3\frac{1}{4}$ and $4\frac{1}{4} \times 3\frac{1}{4}$),

Fig. 19.

and is furnished with a doublet lens, which is used with full aperture. The mode of holding the camera, when being used, is shown in the cut.

Rouch & Co. also show portable chemical laboratories; a changing box for a camera, which can be made to hold any number of plates, the number being determined by the weight; and a pocket camera.

Fig. 20.

Fig. 21.

Fig. 22.

The above figures represent respectively the objects just spoken of.

This firm also exhibit their well-known studio and field cameras and other appliances, together with a magnificent display of photographic chemicals of every nature.

Kawson & Swan have an attractive stand with a varied exhibit, consisting of chemicals and preparations pertaining to photography, cameras, stands, washers, Bracher's new metal dark slides, Bracher's distilling apparatus, instantaneous shutters, a series of cloud negatives, bouquets of artificial flowers and grasses for studio use. An important feature with this firm is the introduction of bamboo and

other light studio fittings. Winter's automatic hand camera is also among the exhibits, a full description of which will shortly appear in our columns. Templeton's oxyhydrogen lamp is also shown, a cut of which appears below.

Fig. 23.

This lamp is fitted for photo-micrography and surgeon's use. By means of parallel rods this light is capable of movement in a backward or forward, horizontal, or up-and-down motion.

A very varied exhibit is shown by Walter Tyler, London. His grand triple lantern has an imposing appearance. It is fitted with telescopic rack fronts and extra large front lenses; several of different foci form part of the adjuncts to this lantern. This, and in fact all his lanterns, can be filled with lime or oil light, those for the latter being ingeniously adjusted for the carrying off of the smoke and heat from the lamps contained in the two lower lanterns. Tyler's helioscopic lantern is so arranged that it can be used as an ordinary lantern or for chemical or electrical experiments. This, too, is fitted for oil and lime lights. Reading lamps, slides of various styles, gas

Fig. 24.

bottles, governors, and gauges, ether saturators and back valves, and a variety of appliances, are included in the display of this firm.

Mr. J. R. Gotz shows several novelties, both in processes and in appliances. Two fine negatives, 15×12 , are exhibited, enlarged from cabinet and quarter-plate by Obernetter's method of direct enlarging. The enlarged negatives are on patent plates, a perfectly even thickness of film being necessary to success. The negatives are exposed in an ordinary enlarging camera, developed with iron, and after washing treated with bichromate of potassium. One part of bichromate with five of nitric acid and five of water form a stock solution; this is diluted fifteen to sixteen times with water, and the plate flooded with it. Then follows resensitising with strong liquid ammonia, '880, one part of ammonia and one of bromide of ammonia in one hundred of water. After washing, and a second exposure in diffused light, the plate is redeveloped with the old developer, which may be strengthened up with new. The image will soon reappear, being built up from below the film; hence density must be entirely judged by transmitted light. The enlarged negatives have the character of originals, and many of them are said to yield better prints than the plates from which they are the copies. The process presents many difficulties, and requires considerable experience, but the results are undoubtedly very fine.

Some prints on Obernetter's gelatino-chloride emulsion paper are shown, as well as on plates (opals), coated with the same emulsion.

Amongst the novelties of the season is Mr. Gotz's "new volute"

shutter, an improvement on his former model. In the new form the mechanism is entirely enclosed in a case of ebonite about two-thirds of an inch thick, and, for a whole-plate lens, about two and a half inches wide by four inches high. The instrument is wound up by means of a small milled head at the back, and may be set to either instantaneous or timed exposures by turning a small crank. A succession of six instantaneous exposures can be made, and about four timed exposures, once the shutter is fully wound up, a distinction which was also a characteristic of the first model, while the new form adds a considerable gain in the rapidity of the instantaneous action. Another shutter is the "Wing," which opens by two metal blades from the centre. Its action is very rapid, and it is constructed for timed as well as for instantaneous exposures at will. Gotz's patent camera is also on view, one single 12 x 10 serving as an illustration of his principle of camera construction, which is distinguished by the erecting arrangements, swing from near the centre of the plate, and the perfect balance of the camera obtained with short focus. The adaptation of his $7\frac{1}{2} \times 5$ size for stereoscopic work will interest those who are desirous of bringing about the revival of this beautiful branch of the art-science.

FIFTY YEARS' PHOTOGRAPHY.

CONTINUING from where I left off in my previous communication, we will for a little consider the work done by the American philosopher, Dr. John William Draper. Allow me in the first instance to show you, by means of the lantern, a portrait of this distinguished experimentalist. Draper was undoubtedly the first to obtain a photograph of the moon. This was secured on a Daguerreotype plate on March 23, 1840. The size of the figure was about one inch in diameter, and the exposure was twenty minutes. This photograph is preserved in the New York Lyceum of Natural History. In Draper's memoirs, published in London in 1878, we find all his early photographic researches given in detail, but we need not go into these. We may, however, refer to his two photometers, the chlor-hydrogen and the ferric oxalate. In the former instrument the measurement of the intensity of the light source was sought to be arrived at by the chemical action which takes place when a mixture of hydrogen and chlorine gases is acted on by light, and in the other, as the name implies, ferric oxalate solution was exposed to light, the quantity of carbonic acid evolved in its decomposition being measured either by volume or by weight. Ingenious as these photometers undoubtedly are, they are nevertheless more scientific than practical. Dr. J. W. Draper may be credited with being the first to produce a print from ferric oxalate. This was in the year 1848. Draper occupied himself much with photo-spectroscopic work, and was the first to photograph what are known as the red lines on the spectrum. This he accomplished by the use of bitumen in India. He was Professor of Chemistry and Natural History in the University of New York, having been appointed to the chair in the year 1853. He died on the 4th of July, 1882.

We come now to the collodion era in photography, and the name which is associated therewith, as most of you are all aware, is that of Frederick Scott Archer. We will have his portrait thrown upon the screen while a few details regarding Archer's career may be appropriately given. In attributing to Archer the merit of originating the collodion process, it is not for a moment to be supposed that he was the discoverer of collodion. This substance was prepared, not long after the discovery of gun-cotton, by Schönbein, and was used in surgery to cover injured surfaces. Archer was in early life apprenticed to a silversmith, and subsequently took to modelling for the trade. He afterwards followed the profession of a sculptor, and many excellent busts were, it seems, modelled by him. In March, 1851, Archer published his account of the collodion process in the *Chemist*, though we have evidence that he had produced pictures by means of collodion in the autumn of 1850. The details of the process we are considering are so intimately associated with even present-day operations that we may be excused going into particulars. Suffice it to say that Archer's process was what really popularised photography. Talbotype and Daguerreotype had of course their votaries, but where one practised these processes, ten and more were to be found following the ever fascinating wet collodion process. As is well known, Archer did not in any way derive pecuniary benefit from his discovery. Unlike some of his predecessors, he gave the results of his experiments free to all the world, benefiting others, for it cannot be denied that many fortunes were made through the instrumentality of his discovery. Archer did not live many years after he had made his free gift to the world. In May, 1857, at the early age of forty years, Archer passed away. Mrs. Archer died very shortly afterwards, leaving three orphan daughters totally unprovided for. Through the exertions of the photographic community a sufficient sum was raised to secure to the family sufficient for their education and upbringing.

The collodion process reigned supreme for many years, but it had its drawbacks as well as its advantages. It was not suitable for outdoor photography, inasmuch as it was necessary to take to the field of operations all the paraphernalia of the dark room. Hence, the desire arose to

produce a plate that could be prepared at home, having the necessary-keeping qualities, so that it could be brought back after exposure for subsequent development in the studio. So much was attempted in that direction that we can do no more than simply refer to one or two of the more prominent processes. Abney, in his article on *Photography* in the *Encyclopædia Britannica* gives the credit to M. Gaudin as being the first to experiment with collodion dry plates. This was in the year 1853, and his researches are detailed in *La Lumière* for that year under the dates of April 23 and May 27. All the collodion dry plate processes devised had a strong family likeness, the plate being coated in the first instance with iodised collodion, afterwards sensitised in a nitrate of silver bath, and finally washed, had what was known as the preservative applied to it, and many were the preservatives put forward from time to time. We may refer to the following: tea, coffee, albumen, tannin, honey, gum arabic, beer and gelatine. Tanpenot's process, which I know was worked by some of our members, was reckoned one of the most reliable of the dry plate processes—in this albumen played the part of the preservative. Again, the gum gallic process, introduced by R. Manners Gordon, was also one giving good results. We will only refer to another, viz., Major Russell's tannin process, and this process leads us to speak of what we now know as the "alkaline developer," for it appears that in 1862 Major Russell introduced it in connexion with the plates prepared by his method. In this developer we have, as is well known, three bodies present—an alkali; a reducing agent, for the most part pyrogallie acid; and a restrainer, a soluble bromide. This developer placed a new power in the photographer's hand, but it was not till the gelatine rapid plate made its appearance that its real importance became manifest.

We will now come down to the year 1861, and in this year we find that a distinct advance was made when Bolton and Sayce brought forward their collodion emulsion process. As is well known, this method did away with the sensitising bath, the sensitive salt of silver being formed in the collodion, and the salts of decomposition removed by washing. The actual gaining sensitiveness was not by any means great, it was rather the reverse; but the method of proceeding when applied to the vehicle gelatine has been the means of giving us all the brilliant results photography has in these latter years achieved. Up to the point we have been considering the iodide of silver had formed the mainstay of the photographer, but with the introduction of the emulsion plate recourse was had to the bromide. Emulsion processes may be broadly classed as washed and unwashed. In the latter the emulsion was washed *in situ* on the plate, in the former the washing was effected on the material as a whole.

Leaving collodion emulsion, and passing on to consider its more successful rival—gelatine emulsion—the first in the field to point out its possibilities was Dr. Richard Leach Maddox. We present you with his portrait. Dr. Maddox in 1871 secured negatives by means of a silver salt emulsified in gelatine. In 1874 Mr. A. Kennett published a formal giving good results, and in 1878 Mr. C. Bennett, a photographic amateur, published results showing how great sensitiveness and rapidity were to be obtained by keeping the gelatine liquid for several days at a low temperature. This mode of obtaining the silver salt in a highly sensitive condition received the somewhat homely term of "cooking." The results obtained by the foregoing experimenters were sufficiently remarkable to bring others into the field, and the consequence was that many modifications were introduced, all having the same end in view, viz., to produce a very susceptible photographic plate. We may simply refer to some of the names associated with this work, the late Dr. von Monckhoven, Dr. H. Vogel, of Berlin, Colonel Stuart Wortley, Mr. W. B. Bolton, Mr. W. E. Henderson, and many others.

There is one investigator who stands out pre-eminently in scientific photography, and who has done much towards clearing up many of the chemical changes involved when light acts on the sensitive gelatine film, I allude to Captain Abney. To appreciate fully the value of the work done by Abney a certain amount of chemical knowledge is necessary. Had he done nothing else, the preparation of his peculiarly constructed form of silver bromide, whereby he was enabled to photograph the red rays of the spectrum and the rays beyond, would have earned him the foremost place. Abney first pointed out the capabilities of hydroquinone as a developer, the point of difference between this substance and the pyro being that while the latter requires the presence of the restrainer, the former can be used *per se*. As I would like to refer to what has been done in processes where silver has not been made use of, and to photo-mechanical processes, we will require to pass on. I feel that I am disposing very summarily of much that is interesting and necessary for a true estimate of the gradual development of that process which has made photography the thing it actually is; but in order that I may not appear before you again this session with another continuation I will try to compress the more salient points still to be touched upon into the narrowest possible limits. A few words, then, in the first instance regarding the carbon process. We have in our first communication already referred to the reaction noted by Munro Ponton of the reduction by light of a bichromate; but another fact has to be recorded, and it is this, that should gelatine, glue, gum, or albumen be present along with the bichromate, these substances become insoluble. Taking gelatine and mixing with it a certain amount of colouring matter, and coating paper with the mixture, thereafter treating it with a solution of bichromate, we find that after exposure to light we are enabled by the dissolving away of the unaltered gelatine by means of hot water to obtain a picture.

Certain precautions are necessary, such as developing from the back, &c., to secure the half tones, but these we need not enter upon, as it is with the history of the subject we are more immediately concerned. Talbot had utilised this property of the insolubility of the altered gelatine for the production of his etched plates in 1853, but Poitevin, a French chemist, patented a carbon process in England in 1855, and Pouncey, an Englishman, published in 1859 a similar process. Half tones were wanting in both processes. It was not till 1861 that carbon printing became an accomplished fact. Mr. J. W. Swan may be reckoned the true pioneer, when he showed how to develop the picture from the back by transferring it to an indiarubber support while developing; he it was who first introduced the now familiar carbon tissue. We have not the time to go into all the simplification of details which has gradually been evolved in the working out of the process, but we may simply refer to Sawyer's flexible support, which was a decided advance, and which was introduced by Mr. Sawyer in 1871. The carbon process remains with us to this day, and judging from the number of pictures on opal plates produced by this means presented for sale in the various shops in Glasgow, it shows no sign of diminishing vitality.

CAMERA CLUB CONFERENCE PAPERS.

II.

SCIENCE AND ART.

By Dr. P. H. EMERSON.

SINCE all mental progress consists, as Mr. Herbert Spencer has shown, for the most part in differentiation—that is, in the analysis of an unknown complex into known components—surely it were folly to confuse any longer the aims of Science and Art. Rather should we endeavour to draw an indelible line of demarcation between them, for in this way we make mental progress, and Science and Art at the same time begin to gather together their scattered forces, each one taking under its own standard those powers that belong to it, and thus becoming integrated, and necessarily stronger and more permanent; for evolution is integration and differentiation passing into a coherent heterogeneity. Now, I do not mean to premise that this confusion between Science and Art exists everywhere; it does not. But I feel sure that it exists largely in the ever-increasing body of persons who practise photography. The majority of these have not thoroughly, nay, not even adequately, thought the matter out. It is obvious, then, according to the teachings of evolution, that, if we are to make progress, this differentiation must be made, thoroughly understood, and rigidly adhered to by every practitioner of photography. Each one must have his aim clearly stamped upon his mind, whether it be the advancement of Science or the creation of works whose aim and end is to give æsthetic pleasure. Proceed we now to analyse the difference between the aims and ends of Science and Art. Let us first approach the subject from the scientific standpoint.

Assuming that we have before us a living man, let us proceed together to study him scientifically, for the nonce imagining our minds to be virgin tablets, without score or scratch. Let us proceed first to record the colour of his skin, his hair and eyes, the texture of his skin, the relative positions of the various orifices in his face, the number of his limbs, the various measurements of all these members. So we go on integrating and differentiating until we find that we have actually built up a science—ethnology. If we pursue the study, and begin to compare different races of men with each other, we find our ethnology extends to a more complex anthropology. We next observe that the eyelids open and close, the lips open, sounds issue from the mouth, and our curiosity leads us to dissect a dead subject; and we find that beneath the skin, fat, and superficial *fascia* there are muscles, each supplied with vessels and nerves. We trace these vessels and nerves to their common origins, and are led to the heart and brain. In short, we find the science of anatomy grows up under our hands, and if we go on with our studies we are led into microscopy. Then we begin to ponder on the reasons why the blood flows, on the reasons why the *corrugator supercilii* and *depressor anguli oris* act in weeping, the *musculus superbus* in practical arrogance, and the *luratur anguli oris* act in snarling or sneering. So we go on studying the functions of all the organs we find in our man, and, lo! we are deep in physiology; and if we go deeply enough, we find the thread lost in the most complex problems of organic chemistry and molecular physics. And so we might go on studying this man; and if our lives were long enough, and if we had capacity enough, we should be led through a study of this man to a knowledge of all physical phenomena, no wonderful and beautiful is the all-pervading principle of the conservation of energy, and so indestructible is matter. As we proceeded with our studies we should have been observing, recording, positing hypotheses, and either proving or disproving them. In all these ways we should have been adding to the sum of knowledge, and in the greatest steps made in our advancement we should have made use of our constructive imagination—the highest intellectual power, according to recent psychologists.

The results of these investigations, if we were wise, would have been recorded in the simplest and tersest language possible, for such is the

language of Science. It is needless to point out that in these records of our studies, as in the records of all scientific studies, too many facts could not possibly be registered. Every little fact is welcome in scientific study, so long as it is true. And thus the humblest scientific worker may help in the great work; his mite is always acceptable. Such is, alas! not the case with that jealous goddess, Art; she will have nothing to do with mediocrity. A bad work of art has no *raison d'être*; it is worse than useless—it is harmful. To sum up, then, "Science," as Professor Huxley says, "is a knowledge of the laws of Nature obtained by observation, experiment, and reasoning. No line can be drawn between common knowledge of things and scientific knowledge, nor between common reasoning and scientific reasoning. In strictness, all accurate knowledge is Science, and all exact reasoning is scientific reasoning. The method of observation and experiment by which such great results are obtained in Science is identically the same as that which is employed by every one every day of his life, but refined and rendered precise."

Now let us turn to Art, and look at our imaginary man from the artistic standpoint. Assuming that we have learned the *technique* of some method of artistic expression, and that is part of the science we require, we will proceed with our work.

Let us look at the figure before us from the sculptor's point of view. Now, what is our mental attitude? We no longer care for many of the facts that interested us when we were studying the man scientifically; we care little about his anatomy, less about his physiology, and nothing at all about organic chemistry and molecular physics. We care nothing for his morality, his thoughts, his habits and customs, his sociological history, in fact; neither do we care about his ethnological characters. If he be a good model, it matters little whether he be Greek, Italian, or Circassian. But we do care, above all, for his type, his build, and the grace with which he comports himself; for our aim is to make a statue like him, a statue possessing qualities that shall give æsthetic pleasure. For the *raison d'être* of a work of art ends with itself; there should be no ulterior motive beyond the giving of æsthetic pleasure to the most cultivated and sensitively refined natures.

The first thing, then, we must do is to sit in judgment on our model. Will he do for the purpose? Are his features suitable? Is he well modelled in all parts? Does he move easily and with grace? If he fulfils all these conditions we engage him. Then we watch his movements, and seize on a beautiful pose. Now with our clay we begin to model him. As we go on with our work we begin to see that it is utterly impossible to record all the facts about him with our material, and we soon find it is undesirable to do so—nay, pernicious. We cannot model those hundreds of fine wrinkles, those thousands of hairs, those myriads of pores in the skin that we see before us. What, then, must we do? We obviously select some facts—the most salient, if we are wise—and leave out the rest.

All at once the fundamental distinction between Science and Art dawns upon us. We cannot record too many facts in Science; the fewer facts we record in Art, and yet express the subject so that it cannot be better expressed, the better. All the greatest artists have left out as much as possible. They have endeavoured to give a fine analysis of the model, and the Greeks succeeded.

It is beside the question to show how Science has exercised an injurious influence upon certain schools in art, but that would be very easy to do. At the same time the best Art has been founded on scientific principles—that is, the physical facts have been true to nature.

To sum up, then, Art is the selection, arrangement, and recording of certain facts, with the aim of giving æsthetic pleasure; and it differs from Science fundamentally, in that as few facts as are compatible with complete expression are chosen, and these are arranged so as to appeal to the emotional side of man's nature, whereas the scientific facts appeal to his intellectual side.

But, as in many erroneous ideas that have had currency for long there lurks a germ of truth, so there lurks still a leaven of Art in Science and a leaven of Science in Art; but in each these leavenings are subordinate, and not at the first blush appreciable. For example, in Science the facts can be recorded or demonstrated with selection, arrangement, and lucidity—that is, the leaven of Art in Science. Whilst in Art the physical facts of nature must be truthfully rendered—that is, the leaven of Science in Art.

And so we see there is a relationship between Science and Art, and yet they are as the poles asunder.

(To be concluded.)

Foreign Notes and News.

THERE appeared in a late number of the *Bulletin de la Société Française de Photographie* a description of a method for removing the so-called dichroic film on negatives, that appears red by transmitted, and green by reflected, light. The negative is plunged for some minutes into water, and afterwards, for some twenty to forty seconds, into a solution of 2 : 100 of perchloride of iron; then, without washing, into a solution of fresh hyposulphite, and finally washed in a copious supply of water. The film

in question has only been found to appear when alkaline developers have been allowed to act too long upon negatives that had been insufficiently exposed in the camera, and even then only with quick-acting emulsions.

THE entrance of instantaneous photography into the domain of diplomacy would seem to mark an epoch in the history of the art; at any rate, it is an excellent proof of the lofty position which it has succeeded in gaining for itself in the modern world. The German Emperor was anxious a short time back to obtain some photographs of the ambassador and his suite, who had arrived in Berlin with the presents sent to the Emperor by the Sultan of Morocco. The law of Mohammed, however, expressly forbids his disciples to permit any kind of effigies of their persons to be produced, whether by the brush of the artist or the camera of the photographer. What was to be done? The Emperor appears to have been pressing, the ambassador unwilling to commit sin. The Gordian knot was cut by two ingenious courtiers—Count Kanitz and Count von Lütichan. The court photographer, at their suggestion, placed himself in ambush, and at the proper moment after the presentation pressed his trigger and took a pistol photograph of the unwitting follower of the Prophet!

THE last general meeting of the *Amateur Photographic Club* of Vienna seems to have possessed more than the usual interest of such reunions. Prof. O. Simony had just returned from the Canary Islands, of which he gave an entertaining account; while Dr. Jnl. Hofman exhibited a number of photographs and reproductions which he had taken by the magnesium flash lamp from coloured originals, and made an explanatory series of remarks which appear to have occupied a considerable time. The patience of the audience was, however, at last rewarded by the exhibition of the very interesting photographs which Dr. Seolik had taken of pre-Christian inscriptions, more especially of cuneiform characters discovered on bricks from Southern Babylonia, and which he elucidated with considerable erudition.

ACCORDING to the *Moniteur de la Photographie*, M. Block, jun., of Paris, by an ingenious arrangement known to many of the old collodion workers, has succeeded in rendering visible the development of a negative to a whole class. The negative was placed in a vessel with parallel sides of red glass, into which the developing fluids were introduced, and the whole projected on a screen by the oxyhydrogen light.

A BERLIN society, whose object is the providing of suitable work for ladies and girls of the better classes, has decided to select photography as one of the most suitable kinds of employment, and has arranged for a quarterly course of instruction and lectures in the art-science.

HERR C. LIEBERMANN, of Alizarin, has lately succeeded, by means of reduction with ammonia and zinc, in preparing a new body of a yellow colour, which he calls anthrarobin, and which, especially in alkaline solutions, possesses the power of absorbing oxygen in a high degree. Anthrarobin, though not soluble in water, dissolves in alkalies, and still better in alcohol and gelatinous acetic acid. As, however, gelatine plates are always developed with alkaline solutions, an experiment with anthrarobin would be well worth trying for this purpose, especially as only dilute solutions of alkalies are required to dissolve it. Anthrarobin solutions, however, require constantly to be prepared afresh, as they do not keep well.

A FORMULA has been communicated to the French Society of Photography by M. Ottenheim for development, by means of combined hydroquinone and pyrogallie acid; the following solutions, which keep well, should be prepared beforehand:—

Solution A.	
Water	340 grammes.
Carbonate of soda	50 "
Sulphite of soda	25 "

To be mixed while hot, and 5 grammes of hydroquinone to be added after filtration.

Solution B.	
Water	375 grammes.
Sulphite of soda	50 "
Pyrogallie acid	7.5 "
Sulphuric acid	3 drops.

To develop, take 55 c.c. of A, and 15 c.c. of B.

M. Ottenheim produced some negatives developed by means of these solutions, which were found to be very clear and vigorously defined.

DR. DRONER, of Berlin, has been recently pointing out a new method by which the assistance which has so frequently been rendered in the past by photography to various practical sciences has received a still wider

extension. Instantaneous photography has, according to him, proved itself of great value in experiments on the strength of building materials, and seems likely to do so still more in the future. In testing the breaking strain of a steel bar, either by pressure or strain, it is often of great importance to fix exactly the instant when the piece of metal gives way. On subjecting a piece of metal to pressure, the question arises, What alterations of form take place in the metal at the time, and what alteration of form occurs when the metal is slowly released from this pressure? The assistance of instantaneous photography has proved of value in furnishing answers to both these questions.

DR. C. ARNOLD, of Hanover, recommends, in the February number of the *Photographische Mittheilungen*, the employment of pyrocatechin as a developer. For plates of a size up to 18 x 24 centimetres he employs a mixture of 0.05 grammes pyrocatechin and 5 grammes of carbonate of potash dissolved in a proper quantity of water. As pyrocatechin is more easily soluble than hydroquinone, he employs when travelling a solution of soda of suitable strength, and adds to it when required as much pyrocatechin as will go on the point of a penknife, which is easily dissolved by shaking the bottle. This new developer possesses all the advantages which the inquirer in *Nature* has observed, especially the capacity of causing a clean and regular development, so that even when the solutions are comparatively cold the process still takes place with comparative rapidity. The plates when developed may, after washing, be fixed in ordinary daylight. According to the intensity of illumination the amount of carbonate of potash in solution must be increased or diminished. Bromide of silver, gelatine paper, and diapositives may be treated with the same developer as above. Should pyrocatechin become more generally employed, Dr. Arnold seems to think that its price would soon fall to the level of that of hydroquinone.

JUDGES' AWARDS. R. W. THOMAS & Co.'s COMPETITIVE EXHIBITION, Crystal Palace, March 19 to April 13, 1889.—Judges, Messrs. J. Gale, G. Davison, and Andrew Pringle. *Class I. Portraiture (including groups)*. Silver medal, W. H. Banks, Trinity College, Cambridge; bronze medal, the Rev. F. C. Lambert, 62, St. Andrew's-street, Cambridge.—*Class II. Landscape (including figure subjects)*. Silver medal, S. D'Arcis, 6, Brent Villas, Hendon; bronze medal, Alexander M. Morrison, 10, Renfrew-street, Glasgow; honourable mention, the Rev. F. C. Lambert.—*Class III. Architecture (including interiors)*. Silver medal, J. T. Hopwood, Kilton Hall, Stamford; bronze medal, the Rev. F. C. Lambert.—*Class IV. Instantaneous Photography*. Silver medal, no award; bronze medal, Jerome Harrison, 365, Lodge-road, Hockley.—*Class V. Lantern Slides*. Silver medal, Low Sergeant, South Norwood; bronze medal, M. J. Harding, College-hill, Shrewsbury.—*Gold Medal for the best Photographic Work*: J. T. Hopwood.

PATENTS COMPLETED.

AN IMPROVED DARK SLIDE FOR PHOTOGRAPHIC CAMERAS AND IMPROVEMENTS IN CAMERAS TO BE USED THEREWITH.

No. 5462. ANKETELL MATTHEW HENDERSON, 20, Avoca-street, South Yarra, Victoria.—*April 12, 1888.*

My invention consists first and mainly of an improved dark slide for photographic cameras, and secondly of certain improvements in such cameras, to be used in connexion with my dark slide, although such slide can be used with any kind of square bellows camera or any box or detective camera of sufficient depth.

The dark slide consists of a flat box or tray containing a number of carriers or frames for holding the sensitive plates or films. These carriers or frames can be made of metal, cardboard, wood, or other suitable material. Each carrier or frame is hinged on a pin, which passes through the sides of the box or tray, and has at one end a bent arm or other contrivance by means of which the carrier or frame inside can be swung or partially revolved, and these pins are so arranged that each plate can be swung or revolved about ninety degrees. This is done by arranging the line of pins at an angle of forty-five degrees with the ends of the dark slide which is fitted with the usual sliding or folding shutter, which can be opened when the slide is in position in the camera, and this shutter if sliding may be made to remove altogether from the dark slide, and to hold it when so removed I provide small clamps on the back of the dark slide. The dark slide may be made to slide into grooves in the back of the camera, or to slip between the ground glass and the camera back, or to fix to the back with clamps as may be found most convenient, or the dark slide may be made of sufficient depth to form a box camera. The dark slide is used as follows:—

When the sliding or folding shutter is removed the exposure of the front plate is made in the camera in the usual manner. This plate, then, by means of the bent arm on the pin is turned at right angles into the body of the camera, thus presenting the back and edge of the carrier or frame to the lens, and exposing the sensitive plate or film in the next carrier or frame. Before exposing this film, the lens or dark slide must be brought nearer to the extent of the thickness of the carrier or frame. To do this accurately I use a scale on the sliding part of the camera or on the lens, the lines on which correspond with the thickness of the carriers or frames. For detective cameras, where focussing is performed by estimating the distance of the view or object from the camera, I use a double scale, the division of the one corresponding with the thickness of the carriers or frames, and the divisions on the other representing the alterations of focal lengths at the varying distances of the view or object. These are fitted to the sliding body of the camera or to the lens, as may be most convenient, so that by bringing the line representing the distance in conjunction with the line representing the plate or film whose surface is exposed the image cast by the lens on the surface will be in focus.

To provide against the access of light to the edges of the plates when the carriers or frames are turned out into the body of the camera I use a shutter hinged to a pin passing through the front of the camera, and fitted with a bent arm or other contrivance by means of which the shutter can be hinged or revolved so as to cover the backs and edges of the carriers or frames and prevent access of light to the edges, and this shutter can be made with the edges turned back like an inverted tray for greater security. Where the lens projects inside the front of the camera I make the centre of this shutter of pliable material. To further protect the plates from light I line the inside of the dark slide and the portion of the camera into which the plates project with velvet or similar material, and when the dark slide is made for use in a bellows camera I hinge in front of the front carrier or frame a tray which can be turned out into the body of the camera to enclose the plates or carriers when so turned out.

To hold the carriers or frames in their places in the dark slide parallel to each other I use various contrivances. For small plates or films I use an arm fitted with a spring and hinged to a pin passing through one end of the dark slide, and fitted with a bent arm or stud for partially revolving same. When the arm is turned out into the camera each plate in turn can be released, and the spring forcing back the arm against the remaining carriers or frames will hold them in position. Another method is to have a catch plate of wood or metal covered with velvet or similar material at one end of the dark slide held in contact with the carriers or frames by a spring. This catch is attached to a pin passing through the end of the dark slide so that it can be drawn back when desired to release the carriers or frames. I use sometimes V-shaped studs or a rack on the bottom of this catch plate to hold the carriers in exact position. For large plates or films I prefer a similar catch plate for each carrier or frame, each fitted with a pin passing through the end of dark slide and arranged over each other, so that raising an inner catch will raise all the outer ones also. As before mentioned, the dark slide can be used in any square bellows camera or box or detective camera of sufficient depth, but I prefer to use one of the special cameras, hereafter described.

For a detective camera I use a sliding box camera, and place the sensitive

plates or films in the carriers or frames so that their centres are in a line parallel with the sides of the camera. Where a lens of short focus is used, I project the portion of the camera front into which the carriers project so as to allow room for them.

For travelling cameras I place the plate or films in the carriers with their centres parallel with the centres of the pins on which the carriers revolve, and I carry the lens on a front which moves parallel to these pins. In the first camera this is done by attaching the front to parallel links and holding it at the correct focal distance by a link attached to the top with lines marked thereon, or holes bored therein at distances corresponding with the various films or plates. In the former case the double scale already described is used, in the latter case a pin on top of the camera is provided which fits into the holes, and thus holds the front at a correct focal distance. This pin can be made to slide so as to adjust the front for varying distances of the view or object. The rest of the body of the camera I make of pliable leather or cloth, or indiarubber cloth.

In the second camera I use, the lower part of the front is hinged to the upper, and opens parallel to the line of pins of the carrier or frames. The lens is fixed in a sliding plate on the front, fitted with a double index as before described. The lower part of the body I make of leather cloth or similar material.

IMPROVEMENTS IN DARK SLIDES OR PLATE HOLDERS FOR PHOTOGRAPHIC CAMERAS.

No. 6992. MICHAEL TAYLEURE, Market Place, Pocklington, Yorkshire.—*May 10, 1888.*

The invention relates to that part of a photographic camera known as the dark slide or plate holder, which is used to contain and transport the sensitised plate. I construct my slide in a special and peculiar manner so as to be perfectly light-tight. It may be single or double and the shutters may be specially constructed so as to draw right out, a great advantage for landscape work on a windy day.

The invention is specially applicable for dry plate photography, and the slide may be made of tin or other suitable material. The special construction of the slide is a feature of the invention.

The mode of action is as follows:—

Draw out the slides, which are curved at the top where the rings are; the latter are provided for the purpose of keeping the indiarubber in its place, as well as to exclude the light from the plates when in use. When drawing out the slide facing the lens with one hand, place the other hand upon the other slide to keep it in its place.

After drawing the slides out to charge the slide with fresh plates, place the sensitised plates back to back with a piece of card the size of the plates between, as seen in the sample sent, so as to keep the other plate secure from the light.

The slides will pack in a small compass, and no dark room or tent is required.

Having now particularly described and ascertained the nature of the said invention, and in what manner the same is to be performed, I declare that what I claim is:—1. A dark slide or plate holder in which the orifice of the slot, into which the shutter or shutters are passed, is closed by elastic or springy material when the shutter is not in position, but which yields to the pressure of the shutter when the latter is pushed in, and swells out, filling the slot, and keeping the light excluded as the shutter is withdrawn, whereby the shutter can, if it be desired, be entirely withdrawn, without permitting the entrance of light through its slot. 2. A dark slide or plate holder for photographic cameras in which a flat frame, divided into separate compartments by the removable partition, and having guides or channels, and an elastic roller or spring, is adapted to receive the sliding shutters on each side of the partition aforesaid, whereby said shutters can be completely drawn out when it is desired to uncover the sensitised surface of one of the plates, without the risk of lighting the sensitised surface or film of the other plate, substantially as described.

IMPROVEMENTS IN SPIRIT LAMPS FOR THE RAPID AND PERFECT COMBUSTION OF MAGNESIUM POWDER WITHOUT PERCEPTIBLE SMOKE FOR PHOTOGRAPHIC PURPOSES.

(Communicated to me from abroad by John William Charles Coven Schirm, Professor, of Breslau, in the Empire of Germany.)

No. 1504. EDMUND EDWARDS, 35, Southampton Buildings, Chancery-lane, Middlesex.—*January 28, 1889.*

This invention relates to improvements in spirit lamps for the rapid and perfect combustion of magnesium powder for photographic purposes, and it has for its objects—first, the reduction of the quantity of magnesium used, by perfect combustion, to such a minimum that no inconvenience whatever from smoke or noxious vapours is experienced even in the smallest room, without, however, in any way diminishing the photographic power of the light below the quantity necessary for photographic purposes; and second, the construction of the lamp so as to render its use perfectly safe, and to prevent all danger in case of accident, making its transport from one place to another perfectly safe and easy.

The lamp consists of a hollow metal or glass body filled with compressed sponge or spongy matter and having an opening closed with wire gauze. To the body of the lamp is fixed, by means of a pin, a small brass tube, bent up rectangularly and widened to a small conical receptacle at its end, and connected at its other end with a pneumatic ball, or other apparatus, by means of an indiarubber tube.

The sponge of the lamp being saturated with spirits of wine and the lamp ignited, it will burn with a long blue flame using very little material, and on account of there being only enough spirits of wine to saturate the sponge the lamp will, if knocked over by accident, go out immediately, and in no case will any spirit of wine run out and cause any danger by ignition. By turning a small brass tube round its pin the funnel is brought out of the flame and a small quantity of magnesium powder (about two centigrammes) is filled into it and then the whole is turned back again into the flame.

At the moment in which, by pressure on the pneumatic ball or equivalent apparatus, air is sent through the brass tube, the magnesia powder is blown through the axis of the flame and the latter itself is at the same time, by the strong current of air, sent through its whole length greatly augmented, and its heating quality is at this instant so increased as to render the combustion of the magnesium powder complete, and more perfect than in any other lamp, especially of the kind having a circular wick and current of air through the centre, as in these lamps the blowing through of more air than is necessary for the flame, in order to increase its heating quality, only diminishes it, and so widens the opening in the circular flame that a great part of the magnesium powder is blown through this opening without being ignited.

On account of the combustion of the magnesium powder in the present lamp being so perfect, it is possible, without decreasing the power of the light below the amount necessary for photographic purposes, to diminish the quantity of magnesium powder to such a minimum that no smoke is perceptible and no inconvenience whatever is experienced from it even in the smallest room, and after a number of flashes from two or more lamps.

Thus all cumbersome apparatus for conveying away the smoke, necessary with other lamps, is avoided, as also the danger generally accompanying spirit lamps, thereby giving the possibility of taking photographs in any room and at any place without the slightest inconvenience or danger.

Several lamps may be connected by India-rubber tubes to one and the same pneumatic ball, thus enabling the operator to produce the flash exactly at the same time at two or more places, and, by suitable disposition of the lamps around the object to produce a light equal in every respect to good daylight.

Having now particularly described and ascertained the nature of the said invention, and in what manner the same is to be performed, I declare that what I claim is:—An improved spirit lamp for the complete combustion of magnesium powder without perceptible smoke, the lamp being so constructed as to avoid all danger in case it is accidentally upset, substantially as described and shown in an accompanying drawing.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
April 14	North London	Madison Hall, Upper-st., Islington
" 15	Glasgow & West of Scotland Am.	20, West Regent-street, Glasgow.
" 16	Bolton Club	The Studio, Chancery-lane, Bolton.
" 17	Bristol and W. of Eng. Amateur	Queen's Hotel, Clifton.
" 17	Bury	
" 17	Barnley and District	Mechanics' Institution.
" 17	Hyde	
" 17	Manchester Camera Club	Victoria Hotel.
" 17	Edinburgh Photo. Club	5, St. Andrew-square.
" 17	Photographic Club	Anderson's Hotel, Fleet-street, E.C.
" 18	London and Provincial	Masons Hall Tavern, Basinghall-st.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

LAST TUESDAY.—Mr. James Glaisher, F.R.S. (President), in the chair.

A discussion took place about the giving of medals at the Annual Exhibition of the Society, in which discussion Messrs. J. Traill Taylor, W. Bedford, W. S. Birt, Friese Greene, Chapman Jones, T. Samuels, George Davison, T. Sebastian Davis, W. E. Debenham, A. Cowan, and Herbert Fry, and Captain Mantell took part. It was eventually resolved to advise the Council to resume the giving of medals, and arrangements were made to place the nomination and election of jurors in the hands of the members at large, in accordance with one of the new rules. The meeting recommended that the seven jurors should consist of five members of the Society and two non-members, to give opportunity for the invitation of two eminent artist-painters to act. Nineteen members voted for the resumption of the medal system, and five against the resumption.

Mr. JOHN STILLER read a letter from Colonel Waterhouse, dated Calcutta, March 20, setting forth that he had been trying experiments on the photographing of the lines of the ultra red end of the spectrum; he had tried alizarine blue and anthracine blue for the purpose—strength, one in ten thousand parts of water, with one per cent. of strongest liquid ammonia in both cases. The resulting plates gave strong sensitiveness from C to A of the spectrum, and beyond to Z. He had not tried their full capabilities; they seem to be insensitive to yellow, and can be worked in an ordinary dark room without fog; in copying work they give increased sensitiveness to red. He had also tried rhodamine, an amido-phenolphthalein, which gives a vivid fluorescence not destroyed by acids; its sensitiveness to yellow is scarcely equal to erythrosine. He considered that something was wanted to supplant eosine, the use of which was somewhat blocked by patents.

At the suggestion of the PRESIDENT, discussion on this communication was adjourned until the next meeting, when he hoped that Captain Abney would be present.

Mr. SPILLER added that Colonel Waterhouse also stated that no doubt the French patent had been the making of orthochromatic photography.

The President exhibited a photograph of the stars in Cygnus taken by Mr. Isaac Roberts at Maghull.

Mr. FRIESE GREENE then read a paper on *Some Effects probably due to Phosphorescence, Electricity, and Colour Sensitiveness*. At the close he performed two experiments, in one of which he placed two bars of soft iron opposite each other, and between their two ends placed at right angles a damp sensitive gelatine plate, wrapped loosely with folds of opaque paper to protect it from light. An intermittent current was sent, by means of a make-and-break commutator, through two long coils of insulated fine wire surrounding

the two iron bars. A strip of platinum foil on opposite ends of the damp sensitive film enabled the latter to complete the circuit of a bichromate battery. The result was that there was some feeble reduction, occupying an oval space about as big as an egg, between the ends of the two platinum strips, but where the magnetic force was most concentrated in the centre of the oval was a jet black spot, about as big as a pea, between the poles of the two electro-magnets. In his next experiment he used an ordinary sensitive plate, which had been treated with the following solution:—

Nitrite of silver	10 grains.
Cyanine	10 "
Glacial acetic acid	2 minims.
Commercial decoction of horse-chestnut bark	1 ounce.

One drachm of the above was mixed with twenty ounces of water and one drachm of ammonia; the plate was soaked in this for two minutes, then well washed and dried. Such plates, he said, must be prepared with care, as they have a tendency to fog and to show dust spots, but they will photograph far down into the red end of the spectrum. By experiment he proved to those present that the plates had the latter power.

The discussion of Mr. Greene's paper was also adjourned.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

APRIL 4.—Mr. J. Moran in the chair.

The Hon. SECRETARY read a letter from Mr. A. L. Henderson, expressing regret at inability, because of doctor's advice, to attend the meeting to say "Good-bye" before his departure on the following day for Australia.

Mr. COWAN exhibited some prints on opal developed with quinol, saying that the latter developer answered that purpose as well as ferrous oxalate and gave less trouble. He also exhibited quinol and pyro-developed negatives produced in comparative experiments under similar conditions, with the result that he preferred pyro for the purpose.

Mr. A. HADDON said that some doubt had been expressed at the last meeting about Mr. Harrison's statement that the electric lamp at St. Katherine's light-house, Isle of Wight, gave the light of seven million candles, but that when they considered that the light was measured after being collected by optical apparatus and sent out in one narrow horizontal beam, it did not seem so strange.

Mr. W. H. HARRISON remarked that his original statement was that two members of the engineering staff at Trinity House had told him, for the purpose of publication, that it was the most powerful electric light in the world, and gave the light of seven million candles; also that the exact figures, if there were any error, would probably be found in Sir James Douglass' lecture delivered a few days before at the Royal Institution. He (the speaker) had seen the carbons used, and they were thicker than his wrist.

A question in the box said that supposing a large number of negatives two inches square to be taken and enlarged to lantern-plate size, also a similar number four inches square and reduced to lantern-plate size, would there be much perceptible difference in the quality of the results when the positives were projected on the screen, because this point affected the weight of tourists' baggage?

Mr. COWAN replied that the four-inch negatives would give decidedly the best results. In some negatives of animals at the Zoological Gardens, which somebody had taken on excessively small plates, the particles of emulsion produced a visible grain on the screen when enlargements had been made as stated.

Mr. W. E. DEBENHAM thought that there would be no perceptible advantage with the four-inch plate; the difficulty mentioned by Mr. Cowan could be overcome by using a fine emulsion.

Mr. E. CLIFTON remarked that any spots on the smaller negatives would be enlarged.

Mr. DEBENHAM replied that if a particle of dust were floating about, it would be more likely to fall on a four-inch than on a two-inch plate. Optical advantages were on the side of the smaller lens required by the smaller plate.

Mr. W. BEDFORD said that the smaller lenses worked more quickly and gave greater depth of focus; altogether he thought the advantages to be in favour of the smaller camera.

Another question was, "What is the cheapest solvent for celluloid?"

Mr. PRESTWICH thought a solution of camphor in alcohol might answer.

Mr. BEDFORD suggested acetone, which was a powerful solvent of resins, but not particularly cheap.

Mr. William England exhibited prints from negatives of photographic cameras which he had taken by the flash light.

Mr. HADDON exhibited one of Cagniard Latour's small sirens and explained its construction.

The ordinary lantern night meeting of the Association was postponed until the 15th instant.

CAMERA CLUB.

On Thursday, the 4th instant, Sir DAVID SALOMONS read a paper on *Universal Formulas for Enlarging and Reducing*; Mr. E. Ferrero occupied the chair.

Previous to the lecture Mr. Charlton Wollaston exhibited an ingenious hand camera from Messrs. Robinson's, constructed to carry the same spool as the Kodak; the Chairman drew attention to a cheap and handy lantern-slide box; and the Hon. Secretary handed round some specimens of Mr. Blanchard's platinum black process.

In his address Sir David Salomons showed the working out of his formula, which was devised to give the exposure for any variation of light and density of negative, factors being introduced to give the value (ascertained by previous experiment) of these variables. The formulae were said to be most suitable for artificial light work where the light might be considered constant, but could be used for daylight by the working of an actinometer. Some doubts were expressed as to the possibility of fixing accurately and with facility values for

light and density under different conditions, but the lecturer stated that the formula had been found of great practical value in actual working.

Thursday, the 18th instant, will be a lantern evening. In addition to other work which members are invited to bring, the series prepared by the Boston Photographic Society, illustrating Boston, U.S.A., now in circulation in England, will be shown.

NORTH LONDON PHOTOGRAPHIC SOCIETY.

APRIL 2.—Mr. J. Traill Taylor (President) in the chair.

The HON. SECRETARY (Mr. N. P. Fox) read a paper on *The Three Modifications of Platinotype* and demonstrated the hot bath process. In reply to a question, he said that the hot bath process would be most useful to any one who only wanted to develop a few prints occasionally, as the platinum salt being in the developer of the cold bath, and not keeping well longer than a day, made it very expensive unless two or three dozen prints were treated at a time.

Mr. J. OAKLEY called attention to the fine effects obtained with the Eastman bromide paper when using the hydroquinone developer, the image being softer and of a warmer colour.

Mr. L. MEDLAND found a great advantage in soaking dry plates in an old solution of hydroquinone to commence the development, finishing with a fresh solution.

The next meeting will be on Tuesday, April 16, when Mr. Freshwater will exhibit a series of lantern views taken in India; there will also be a discussion on the hydroquinone developer.

HOLBORN CAMERA CLUB.

APRIL 5.—The annual general meeting was held at the headquarters, 100, High Holborn, when the following were elected officers for the ensuing year:—*President*: Mr. W. Rice.—*Vice-Presidents*: Messrs. G. A. Freeman, B.Sc., F.R.S., and C. H. W. Biggs.—*Committee*: Messrs. Nunn, Dear, Beckford, Smith, Myers, Irving, and Edwards.—*Librarian*: Mr. H. C. Gay.—*Treasurer*: Mr. D. R. Lowe.—*Secretary*: Mr. Fred. Brocas.

The SECRETARY stated that during the last nine months the number of members had increased from twelve to forty-eight, and the Club had a balance of over 10*l.* to its credit. A new set of rules were passed, and it was arranged to hold the first field-day at Richmond on Saturday, the 13th instant.

The following were elected members of the Club:—Messrs. Ernest Benest, W. H. Bois, F. Jackson, A. Newmann, Rev. George William Allen, Messrs. F. W. Edwards, John Raphael, Edward J. Edmonds, A. J. Myers, and J. A. Grant.

EAST DULWICH AND PECKHAM PHOTOGRAPHIC SOCIETY.

At a meeting held at 76, Peckham Rye, on Friday last, April 5, it was resolved that a Society named as above be formed. A Treasurer and Secretary were elected, and a Committee of seven formed, who, with the officers of the Society, proceeded to draw up a set of rules.

The meetings will be held on alternate Fridays during the winter months, and once a month during the summer months. The subscription to be 5*s.* per annum.

During the evening the names of eighteen gentlemen were proposed as members.

The next meeting (in consequence of Good Friday falling on the ordinary meeting night) will be held at 76, Peckham Rye, on Friday next, April 12, at eight p.m., to which gentlemen who wish to support the Society are invited to attend.

Proposals for membership may be sent to the Hon. Secretary, Mr. S. W. Gardner, 7, Barry-road, East Dulwich, S.E.

LEEDS PHOTOGRAPHIC SOCIETY.

FEBRUARY 11.—The President in the chair.

Messrs. Walter Taylor, J. T. Dodgson, and George Campbell were elected members of the Society.

Mr. J. C. THOMPSON then exhibited a large collection of lantern slides illustrative of scenery on the Rhine. The slides, Mr. Thompson explained, were all professional ones.

At the close of the exhibition a discussion on their merits took place.

MARCH 11.—This being the annual lantern exhibition, upwards of four hundred slides were sent in by seventeen members of the Society. From this number two hundred and fifty were selected for exhibition.

The hall was filled with members and their friends, who expressed their appreciation of the exhibition.

LEWES PHOTOGRAPHIC SOCIETY.

APRIL 2.—Mr. T. W. Thornton (President) in the chair.

Mr. E. Hammond was elected a member of the Society.

Mr. J. THURKS read a paper on *Hints to Beginners*, which contained many practical hints to the members who were not beginners. He brought two exposed plates which, at the conclusion of his paper, were developed, one by himself with pyro and ammonia, the other by the President with hydroquinone, both of which turned out to be good negatives, although the pyro-developed one was inclined to be rather thin.

A short discussion followed.

The President showed a negative which had been exposed in a camera with conical bellows and which had parts cut off by them.

Mr. P. Morris showed a photograph of the moon taken with an ordinary telescope; and the Hon. Secretary a changing bag which he used, also some

prints, including one of a train in motion, taken in March with an ordinary drop shutter, developed with hydroquinone.

At the next meeting, to be held on May 7, a demonstration of *Enlarging* will be given by the President.

BOLTON PHOTOGRAPHIC SOCIETY.

APRIL 4.—Mr. E. N. Ashworth presiding.

Mr. Percy Knott was elected a member.

Mr. R. Leigh, who has lately returned from an extensive tour in the United States, and who has made over seven hundred exposures with a Kodak, brought to the meeting some sixty or seventy slides, which were most interesting.

COVENTRY AND MIDLAND PHOTOGRAPHIC SOCIETY.

APRIL 3.—Mr. Councillor Andrews in the chair.

The SECRETARY announced the death of Mr. N. E. Rollason, one of the founders of the Society and its first Honorary Secretary; and a vote of sympathy and condolence with his relatives was passed.

It was decided that, weather permitting, the first excursion of the season should be held on April 25.

The meeting then proceeded to the examination of the apparatus that had been brought for exhibition.

Mr. Sturmy brought, among other things, Beck's detective camera, and gave a demonstration of its working. Other articles shown were Marion's vignette serrator (with the aid of which the Secretary gave a practical lesson in vignetting), Fell's mounting set, Optimus plunge shutter, Optimus wick trimmer, an improved dark slide, and many others of utility.

A number of the pictures sent in for the "Frost and snow scene" competition in *Photography* were on view.

A number of exposures by the magnesium light were then made, the President and Secretary being the sitters.

DARLINGTON PHOTOGRAPHIC SOCIETY.

APRIL 8.—Mr. T. Howlett in the chair.

Mr. Hollis was elected a member.

Mr. W. F. K. STOCK opened a discussion on the advantages gained by the use of hydroquinone over sulpho-pyrogallol as a developer for dry plates, lantern slides, and bromide paper. Several specimens of each were shown, and members stated their experience with each developer.

It was decided that a monthly competition of negatives, prints, and slides be held amongst the members of the Society, the subject to be chosen each month, and that the subject for the present month be "A river scene."

BURNLEY PHOTOGRAPHIC SOCIETY.

APRIL 3.—The President (Mr. J. Butterworth) in the chair.

The following were elected members of the Society:—Mrs. J. O. S. Thursby, Messrs. J. Simpson, W. F. Sagar, R. Robinson, T. Preston, A. Moorhouse, F. Robinson, G. Garner, J. W. Wright, T. Bell, W. Thompson, C. J. Massey, W. Witham, R. J. Hurtle, J. M. Ferguson, and F. Hartley.

The PRESIDENT having briefly related the history of the Society, and explained how the new rooms, with their admirable fittings, would assist those who wished to become photographers,

Mr. W. I. CHADWICK then delivered an admirable address on *Stereoscopic Photography*, explaining the mysteries of binocular vision, by which we see one picture although we look at it with two eyes. This is done by the blending of two images by means of the optic nerve. The stereoscope, in like manner, blends two pictures so that we appear only to see one. Mr. Chadwick described the best methods for taking pictures in the camera, and exhibited, by means of stereoscopes, several brilliant examples taken by himself in different parts of the country.

At the next meeting, April 24, the President will give a paper, *My Experiences in Egypt*.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

APRIL 4 (extra meeting).—The President (Mr. A. W. Beer) in the chair.

The object of the meeting was to witness the exhibition of the slides sent by the Boston (U.S.A.) Camera Club, entitled *Illustrated Boston*, the explanatory lecture being read by the HON. SECRETARY (W. A. Watts). The series is remarkably well got up, every arrangement for its successful exhibition being made with great care, and is in that respect a model for imitation. The slides are, generally speaking, of good quality, and the whole lecture very interesting.

The synopsis is too long to quote *in extenso*, but beginning with Boston in olden times the first map is shown and contrasted with a map of the present day. The tourist is then carried round the harbour, the docks and ferries; thence to odd bits of old Boston, such as the Old North Church, where the lantern was hung in the belfry as a signal of the movements of the British troops. The public buildings are then visited—Faneuil Hall, the State House, the Post Office; then the educational and literary institutions, such as the High Schools, the Art Museum, Trinity Church, the avenues and parks. "Fair Harvard" follows with its various buildings—the "Longfellow House," the "Silent Cities," the "Summer Pleasures," along the beach, and elsewhere. Old Haunts and Old Houses, which include some, for America, venerable relics, are amongst the most picturesque of the slides sent, and the beauties of the Charles River. There are some sixty-seven slides and a reading an hour and a quarter. The series has been sent, as previously mentioned, to the Liverpool Association in trust for the use of any photographic society on this side of the water desiring to exhibit it, and in the hope that societies in this country may be induced to

prepare similar series of cities or scenery, and in like manner send them to America.

At the close a number of slides by members of the Association were exhibited, and a vote of thanks passed to the Boston Camera Club for their gift, and to the Hon. Secretary for reading the lecture, in acknowledging which he expressed the hope that Liverpool would actively get up a series during the coming summer and autumn, and offered his services in organizing and preparing the requisite description.

Illustrated Boston will be exhibited at the Camera Club, April 18; Glasgow, 23; and Warrington, 30. Applications for the use of the series should be addressed to Mr. W. A. Watts, Highfield-road, Appleton-in-Widnes.

SHEFFIELD CAMERA CLUB.

APRIL 5.—Mr. B. W. Winder, F.C.S. (Vice-President), in the chair.

The following gentlemen were elected members:—Rev. C. Clementson, M.A., Messrs. Frank Harrison, M.R.C.S., J. W. Charlesworth, and R. R. Neill.

Mr. E. HOWARTH, F.R.A.S., then read a paper entitled *Suggestions for a Photographic Survey of Sheffield*. After having pointed out the work which was being done by photography in surveying the heavens, he called attention to the recommendations made at the last meeting of the British Association that local photographic and geological societies should be asked to make a collection of photographs of the geology of their respective districts. As this would require the combined action of geologists and photographers, it was scarcely possible for the Sheffield Camera Club to undertake this work at present; but there was another kind of photographic survey that might properly and successfully be undertaken by the Club. This was the preparation of a collection of photographs illustrating the chief historical, antiquarian, and topographical features of the town and district. Mr. Howarth mentioned many interesting relics of the past of Sheffield that had disappeared, leaving no record, and urged the desirability, while others still remained, of ensuring their permanent record by means of photographic pictures. He then sketched out a plan for carrying this into effect, suggesting that the town and district should be divided into twelve sections, each section being allotted to two members, who should be provided with a map of their section and a memorandum-book giving a list of the places and objects to be photographed; that the first year's operations should be confined to the immediate neighbourhood of Sheffield, but should be extended year by year to embrace all places of interest within a radius of about twenty miles.

In the discussion that followed it was unanimously decided to carry out the plan, and a Sub-Committee was appointed to arrange the details.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

APRIL 4.—Mr. William Lang, jun., in the chair.

Messrs. William Vercel, David R. Clark, M.A., and T. Pent were elected members of the Association.

Mr. LANG then read the second and concluding portion of his paper, *Fifty Years' Photography* (see page 251). As in the previous portion of his paper, Mr. Lang made use of the Association's lantern to show a very interesting series of portraits he had prepared of the various scientists to whose researches the present position of the photographic art is due.

Mr. Paton showed a very fine series of transparencies of marine subjects. These were made by the collodion process and toned with platinum.

The majority of the meeting concurred with Mr. Paton in the opinion that although the collodion process was more troublesome to work than the gelatine, the results obtained, especially when the transparency has to be reduced from a large negative, are very much superior.

PAISLEY PHOTOGRAPHIC SOCIETY.

APRIL 2.—Mr. John Fullerton presiding.

This Society finished up their winter session by a lantern exhibition.

The CHAIRMAN briefly called attention to the photographic exhibition now being held in the Art Gallery, and stated that the Society had made rapid strides in the photographic art, and he was very pleased to find them so energetic in their desire to provide the public with entertainments such as the one they were about to have, and the presence of such a large number clearly proved that their efforts in this department were highly appreciated.

Two hundred and eighty slides were then exhibited by means of a binocular lantern, and were lucidly described by Mr. James Mure.

BRECHIN PHOTOGRAPHIC ASSOCIATION.

APRIL 5.—Mr. W. Jamieson in the chair.

Mr. George Duncan Edzell was admitted a member.

Mr. R. A. SCOTT, M.A. (Junior Vice-President), gave a *Sketch of the Progress of Photography*. He treated of the various processes which have been employed, and of the many difficulties which have had to be overcome, before the science arrived at its present state of comparative perfection.

Some fine specimens of Daguerreotype, calotype, and wet collodion positive processes were shown and much admired, more especially a Daguerreotype of Sir Walter Scott's Monument, Edinburgh, taken by Mr. J. S. Grant in 1847.

The arrangements for a field-day on April 27 were completed, and the meeting adjourned.

SOCIETY OF AMATEUR PHOTOGRAPHERS OF NEW YORK.

MARCH 1, 1889.—The first regular spring lantern slide exhibition of the Society was held at the rooms, 124, West Thirty-sixth street, and comprised fifty slides

contributed to the lantern slide interchange by the St. Louis Camera Club, and seventy by the members of the Society.

The interest shown in lantern slide making is very encouraging to the Committee. From present indications there will be no difficulty in obtaining a fine collection of slides to represent picturesque New York.

MARCH 8.—*Illustrated Boston*, by the Boston Camera Club, was shown before the Society, and comprised sixty-seven views. The description of the pictures was prepared by Mr. Arthur H. Dodd, who was present to read it. Mr. William Garrison Reed has the honour of being the member of the Club who suggested the idea of illustrating the city.

MARCH 12.—The regular monthly technical meeting of the Society was held.

Mr. F. C. BEACH read a paper on the *Effect of Electricity on Dry Plates*, describing a number of scientific experiments.

Mr. Charles Simpson exhibited a peculiar changing bag to be hung from the neck and to be used when in a sitting position.

Mr. DAVID WILLIAMS explained the outfit, which he intends to use during the summer on his trip abroad.

The Chemical Committee read a report on *The Sulphites of Potash*.

Mr. G. D. MILBURN exhibited an improved Bausch and Lomb shutter, having a special air valve device by which the time of the shutter was very easily regulated. He also read a paper on *Enlarging on Bromide Paper*, following it with a successful demonstration, enlarging a child's head two inches in diameter to life size, and used for this purpose the Society's optical lantern with a limelight. An exposure of twenty seconds was given.

The PRESIDENT announced the election of Dr. J. M. Eder, Leon Vidal, A. Davanne, Dr. H. W. Vogel, J. Glaisher, and M. Carey Lea as honorary members of the Society. He also read a few proposed amendments to the Constitution, among which was one allowing amateurs or professionals residing beyond the corporate limits of the city of New York to become corresponding members on payment of a fee of five dollars.

Correspondence.

Correspondents should never write on both sides of the paper.

PLATINUM TONING.

To the Editor.

SIR,—The use of platinum as the toning metal instead of the more usually employed gold is again on the tapis. Mr. Valentine Blanchard is the sponsor of the present process, specimens of which he showed last week at Anderton's Hotel, but without, as far as I can gather, giving any details of his method of working.

Platinum toning has always presented a peculiar fascination to me, and I have frequently experimented with this salt, in the place of gold, as a toning agent for silver prints. I have to confess, however, that up to last autumn my experiments were decidedly not successful. Up to that date I had always employed the salt which is commercially sold, sometimes as platinum bichloride, sometimes as the tetrachloride, and often as simply chloride of platinum. This salt, according to Pizzighelli, is in reality platinum acid ($\text{Pt Cl}_2 \cdot 2\text{HCl} + 6\text{H}_2\text{O}$), and the free hydrochloric acid attacks the silver image. If, however, the platinum salt be neutralised it refuses to tone, being in this state unlike gold, which is probably reduced from the auric to the aurous stage by the addition of the alkalis. Platinum, on the contrary, has to be acidified by some other acid, and remains presumably in the platinum state. Mr. Willis, in his early platinum experiments, found that the platinum salts were not reduced by the proto-salts of the heavy metals, and in order to obtain his platinum image he had recourse to the platinumous salts. Reasoning by analogy, it seemed necessary, in order to get the best toning results with platinum, that the platinumous salts should be used.

It was not, however, till last year, with the advent of the cold bath platinotype process, that any of the platinumous salts came into my hands. Remembering my old deductions, and having them strengthened by the fact that Captain Pizzighelli, in his book on "Platinotype," gives silver as an equally good reducer of the platinumous salts as iron, I proceeded to put my theory to the test of practice. Taking some ordinary plain salted paper, I printed it as usual and then washed it to free it of the free silver; then laying it on a sheet of glass, I brushed it over with the ordinary developing solution, as recommended by Mr. Willis for the cold bath process. This consists of a solution of the chloroplatinite of potassium, and potassic oxalate, and monopotassic orthophosphate. Success was absolute; the red of the silver print changed to platinum black with the same rapidity as does the iron-coated paper of the Platinotype Company. My first prints came out too chalky, for there is a considerable reduction in the detail and half tone, but by carrying on the printing further this can be compensated for and most perfect results obtained, entirely indistinguishable, I believe, from ordinary platinum prints. During the process of toning the print passes through several tones of a pleasant and warm colour, and by using a weaker solution than the above there are under control; but as I consider it necessary for permanence that the image should be entirely formed of platinum, I have always allowed the substitution to complete itself, so that an application of bichloride of mercury does not in any way alter the tone or colour, whereas if any silver were present it would do so by bleaching the metal.

Of course a subsequent hypo bath was necessary to dissolve out the chloride of silver, although even were some hypo left in the print I doubt much whether it would hurt the image. The time of printing is of course considerably longer than with the ordinary platinotype paper, although one has the advantage of being able to see what one is doing during the printing operation, but the results are undoubtedly quite as good.

I contented myself at the time with simply describing the method of working, and showing some specimens (*vide Journal of the Camera Club*, December, 1888, page 177), as I intended to work out a similar process, and what I consider a more useful one—that is, the obtaining of enlargements in platinum. Something of this sort has, I believe, been done in France, but I have never been able to get hold of a description of their method of working; that is to say, whether they employ a platino or platino-salt. I do not foresee any difficulty in converting a developed image, like the Talbotype or Blanquart Errard's process, both of which could be toned with gold into metallic platinum, but have not yet found time to experiment in this direction. But as other workers are now experimenting in this direction, the above hints may be useful as far as regards the printing-out process I have described; success, I can assure every one, is certain.—I am, yours, &c.,

LYONEL CLARK.

Camera Club, April 9, 1889.

HYDROQUINONE DEVELOPER.

To the Editor.

SIR,—The prominence which is everywhere being given to development with hydroquinone, and the many differences of opinion that seem to exist on the matter, induce me to contribute a few lines on the subject, though I confess that my experience has not as yet been very large. There is one point on which all seem to agree, that the new developer gives results resembling wet plates. Now, I feel inclined to ask sometimes whether a good many who make this assertion have had any experience of wet plate work. It seems to me that many imagine that a black image with a great deal of clear glass constitutes the characteristic quality of a wet collodion plate. Now, I worked for many a season wet plates, and I think others who have done so will support me when I say that a real good negative produced by this process contains but very few points of clear glass; indeed, some of the best had a slight grey veil over the shadows. Many authorities on the process, as you will remember, recommended slight exposure to actinic light, and other dodges, for obtaining this effect. It would appear, therefore, that this very clear glass is not an advantage to be sought for, and I am convinced that a better printing negative will be secured if we use hydroquinone without bromide or other restrainer, except sulphite of soda and potash or soda hydrate; this will give a slight grey veil very like wet collodion.

I am sorry to see hydroquinone formulae getting more complicated. What is the use of putting in citric acid, as do Mr. Swan and Mr. Thomas in their latest formulae? There is no doubt Mr. Swan is right in saying that meta-bisulphite of potash has a most retarding effect with hydroquinone—far greater than can be accounted for by the presence of free acid.—I am, yours, &c.,

GEORGE MANSFIELD.

Nass, April 7, 1889.

WHITE OR YELLOW SPOTS ON PRINTS.

To the Editor.

SIR,—Not having seen the prints on which, as described in your last, white or yellow spots appear after finishing or during the final drying, I do not know if my experience will be of any service. Some years ago I was much troubled with the appearance during drying of many white or yellowish spots—most conspicuous in the skies or light parts; the cause succeeded for a long time in evading detection; I went through the whole process myself with care, thinking that they arose from some carelessness of assistants, but for some time nothing could be discovered.

My practice was to dry the prints in a detached building, remote from fire and chemicals, by spreading them on light wooden frames covered with a cheap paperhanger's canvas. It was noticed that the spots were more frequent in damp weather than at other times, and at last the canvas was suspected, and on covering it with clean sheets (from the domestic stores) the spots vanished. It should be remarked that the canvas had been in use for several years, so that there seemed no reason to suspect it, and it still seems to me rather odd that it should have decomposed all at once and so suddenly, for something of that kind appears to have happened. Fresh canvas of a better quality was put on the frames, and the spots disappeared, and have not troubled me since.

I should add that my present practice is to dry the prints on loose cotton sheets (which can be occasionally washed) laid loosely on the old frames.—I am, yours, &c.,

RUSSELL SEDGFIELD.

SPOTS AND STAINS ON GELATINE NEGATIVES.

To the Editor.

SIR,—It was stated a short time ago in your "Answers to Correspondents" that the red silver spots or stains in a gelatine negative could not

be removed without ruining the negative. I am happy to say that such is not my experience, for I have done it many times most successfully, and, on reading the statement above alluded to, I looked up a negative which I knew to be in a bad state with silver stains. I first took a print from it as it was, then treated it as I generally do in such cases, and took a print from it afterwards, both of which prints I submit to your inspection.

Now I will tell you how the plate was treated, so that both you and your correspondents can do likewise. First, I placed the negative for a few minutes in an alcoholic solution of iodine—two or three grains to one ounce—then washed it with water and placed it in the hypo bath—about two ounces to the pint—until the silver stains were removed, then washed and dried in the usual manner. Should this process reduce the density of the negative, it can safely be intensified with mercuric bichloride, and ammonia, or with hydrosulphuret of ammonia. I have done it both ways with success, only the sulphuret-ammonia is so offensive it compels you to do it on the roof.

Although I have given you a remedy for the evil complained of, I consider "prevention is better than cure," and the only safe way to treat gelatine negatives, especially in our moist climate, is to varnish them with a thick collodion first, and then with ordinary spirit varnish afterwards, before even a proof is taken on silver sensitised paper.—I am, yours, &c.,

J. WERGE.

11a, Berners-street, W.

A PHOTOGRAPHIC PUBLICATION FOR JAPAN.

To the Editor.

SIR,—It may be of some interest to your readers to know that a periodical devoted entirely to photographic matters has been started in this country. The name of the paper is *Sashin Shimpo*, which, being interpreted, means "Photographic News." The name of the chief editor is K. Ogawa; the publishing office is Hakubundo. The paper is issued monthly, and the price for a copy is fifteen sen, there being between two and three sen to the penny.

I send you a copy of the first number, warning you that in reading it you must begin at the last page, at the right-hand side of that, and that you must read in vertical lines.

So far as I know, Japan is the only Eastern country in which a journal devoted exclusively to photographic matters has been published by the people of the country, but even this is not the first appearance of such a journal in Japan. *Sashin Shimpo* was published during the years 1881–82. Ogawa was at that time nominally only assistant-editor, but the working of the paper so far depended on him that when, in 1882, he left his country for America the publication had to be stopped. I have seen one volume of this early attempt; it contains, among other things, a very fair portrait of Daguerre.—I am, yours, &c.,

W. K. BURTON.

[A specimen extract from *Sashin Shimpo* is given on another page.—Ed.]

THE BERLIN EXHIBITION.

To the Editor.

SIR,—Will you kindly inform your readers that an exhibition will be held at Berlin in the autumn, to commemorate the jubilee of photography? The exhibition will open on the 15th September and close in the middle of October. Place, the "Royal Academy," Unter den Linden, Berlin. Five divisions will be made—1. History of photography and applications in science and art, industry, engineering, &c.; 2. Portraiture and landscape photography of an artistic value; 3. Photographic printing processes, autotype, collotype, zincotype, photogravure, &c.; 4. Apparatus and chemicals; 5. Photographic literature. The exhibition is open to all comers. There will be awards for specially valuable contributions and superior productions. Particulars will be published later.

I have been appointed collector and agent for Great Britain, and shall be pleased to answer inquiries. Exhibits must be addressed to the Photographic Exhibition, Königliches Academie-gebäude, 38, Unter den Linden, Berlin, W. Intending exhibitors should notify their intention before the 31st of May to me or to Dr. W. Zeuker, Wichmann-str., 17, Berlin, W.

Exhibits must be at their destination by the 31st of August, and should, therefore, be delivered to me by the 15th of the same month.—I am, yours, &c.,

J. R. GORTZ.

19, Buckingham-street, Strand, London, W.C., April 8, 1889.

"SWEATING."

To the Editor.

SIR,—I should like, through the medium of your valuable paper, to call the attention of your readers to an ever-increasing number of photographers (save the mark) who are doing their level best to ruin the profession.

Let me start with a few queries. 1. Are the charges of the average photographer so exorbitant that the trade is to be cut up by capitalists who can and do work for a small percentage over working expenses? 2. Is half-a-crown a dozen for *cartes-de-visite* a fair price for these men to charge? 3. Why do not the Lords' Sweating Commission inquire into the manner in which these capitalists sweat and grind down their *employés*?

This condition of things must do great harm to photographers generally, and the small ones in particular. These sweating photographers are springing up in all directions, and you will find several not a hundred miles from our great business thoroughfares of Regent-street and Oxford-street.

Some of our country brethren may say that the price I quoted in my second query can't pay. It does pay the capitalist, but how about his assistants? I know one or two of these places where the assistants have to work during the summer for twelve or fourteen hours a-day, and for the most miserable salaries. Well, you say, the assistants can leave. Yes; but who will employ them if it is known where they have been working? The assistants are usually from the country, so they naturally do not know who they are going to work for until they are engaged.

Is it not time that public opinion generally, and the opinion of photographers in particular, expressed itself on this condition of things? Probably photographers who are fortunate in having big businesses will say, "How can your half-a-crown a-dozen men hurt us?" They will hurt you, and the future will show it more plainly than any words of mine. They degrade the profession in the eyes of the public. Moreover, the evil is spreading, and some photographers who ought to know better are giving way to the fever, and by means of sweating their *employés*, are, at middle-class prices, giving first-class work. If you do not suffer already you will, and that sooner than you expect. Can some of the readers of your valuable paper suggest a remedy for this state of things? Anyway, I hope the subject will be taken up, and that abler pens than mine will give their views upon this cankerous evil that is threatening to shake the profession to its foundations.—I am, yours, &c.,
FAIR PLAY.

April 8, 1889.

PSYCHIC PHOTOGRAPHY.—A CORRECTION.

To the Editors.

SIR,—In the article on psychic photography in last week's JOURNAL the writer states, on the authority of Mr. Maskelyne, that Mr. Hudson "made every person sign a book, agreeing to ask no questions." In justice to Mr. Hudson will you permit me to say that this is far from correct? I could mention several instances in which no such stipulation was even hinted at, although the parties were complete strangers to Mr. Hudson.—I am, yours, &c.,
GEO. S. THOMSON.
Clifton, April 6, 1889.

[As regards Mr. Hudson's practice in this respect, when his studio was in the Holloway-road, Mr. Maskelyne is quite wrong.—ED.]

TRANSPARENCIES WITH ORNAMENTAL BORDERS.

To the Editors.

SIR,—It is with regret that I find myself under obligation to lodge a protest against the validity of the patent granted to William John Wilson, 1, Chapel-road, Ealing, Middlesex, for "Improvements in Photographic Transparencies." Eighteen or nineteen years ago I made transparencies, using glass plates with ornamental borders. These plates were made for me by Forest, of Liverpool. Various sizes and designs were used.

Mr. Wilson claims as his invention the using of these bordered plates. I have ample testimony to adduce in support of having used glass plates with ornamental borders on which I made photographic transparencies long before Mr. Wilson did so, and on that ground I claim exemption from any patent right of his to stop me from producing such pictures. At that time I made a good many of these transparencies on bordered glasses for ornamental purposes, some of which I had finished in transparent colours, which enhanced their beauty very much.

However, I found that for window decoration they were of little use. As an instance, I fitted up a staircase window of nine panes; the original glass was very finely obscured, and in putting in the transparencies the two glasses were kept a quarter of an inch apart. At top and bottom of each pane were two openings for ventilation. I waited patiently to see how the alternations of damp, frost, and sunshine would affect them. With the returning spring they gave signs of going, and the summer sun completed what winter in its various moods had begun. If this happened with collodion plates, what may we expect with gelatine, which has such a tendency for moisture? I sent a very fine picture of this class to the Earl of Strathmore on a large plate: it was an enlargement of the sundial in front of Glamis Castle.

I also made transparencies on flashed glass, removing the colours by means of fluoric acid, thus having pictures on clear glass with coloured borders. The fluoric acid is very good for making a translucent backing for such pictures.

To-day I have found in my repository of exploded ideas and experiments one of these bordered plates, with the coating of collodion still on it. As the monthly meeting of our society is on Thursday this week, I intend to take the plate with me and make some remarks thereon.

I have no doubt Mr. Wilson knew nothing of what I had been doing nineteen years ago, but that does not alter the facts I have stated. I can believe these plates being introduced commercially may have a good sale for home decoration where damp will not affect them. I wish Mr. Wilson every success in his new venture, but his patent rights I entirely ignore.—I am, yours, &c.,
JOHN ROBERTSON.

Dundee, April 8, 1889.

Exchange Column.

•• No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

Will exchange universal whole-plate studio camera, swing back, two dark slides, for outdoor camera same size.—Address, W. C. B., 25, High-street, Rochester, Kent.

Will exchange a Ross' No. 2 c.-p.-v. lens for modern tourist camera and slides, half-plate; any difference adjusted.—Address, F. SIMCO, Wellingborough, Northamptonshire.

Beck's No. 3 new extra rapid autograph rectilinear portrait lens for cabinet, just cost 11l., f-4; will exchange for first-class studio camera.—Address, W. DAKIN, Photographer, Sheffield.

Wanted, quarter-plate bellows folding camera, in exchange for quarter-plate box camera and lens, rack and pinion.—Address, ALFRED MAYBANK, 40, Crimscott-street, Grange-road, London, S.E.

Will exchange a 8½x6½ camera, head-rest, Shakespeare in forty-two numbers, a snow-scene background, Dryden's *Vivgil*, and *Gil Blas*, for tricycle.—Address, B. RHODES, 30, Eastgate-street, Gloucester.

7½x5 Kinetar camera by Rouch, all movements except reversing back, leather bellows, five double slides, three fronts, whole-plate lens with iris diaphragm, instantaneous shutter, and tripod; exchange for half-plate long extension camera with three double backs and all motions.—Address, JAMES POLLARD, 101, Albion-street, Leeds.

Complete set of apparatus, consisting of 8x5 modern bellows camera, swing back, double back, and carriers, achromatic lens, rotating stops, folding tripod stand, patent circular top, complete in polished wood case; will exchange for double extension half-plate portable set, or for modern hand camera of detective class, or for optical lantern.—Address, CHAS. STICHO, 40, Lansdowne-street, Brighton.

Answers to Correspondents.

•• Communications relating to Advertisements and general business affairs must be addressed to "H. GREENWOOD & Co.," 2, York-street, Covent Garden, London, W.C.

All matters for the text portion of this JOURNAL, including queries for "Answers" and "Exchanges," must be addressed to "THE EDITOR," 2, York-street, Covent Garden, London, W.C. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.

PHOTOGRAPHS REGISTERED:—

M. Guttenberg, Manchester.—Three photographs of the Rev. Dr. Herman Adler, Delegate Chief Rabbi of the Jews of Great Britain.

F. M. Sutcliffe, Whitby.—Three photographs of a model of Whitby Abbey.

E. & H. T. ANTHONY & Co.—Received.

PROVINCIAL.—It will appear next week.

GIAGGIOLO.—A private communication has been sent.

BORE.—Leintypic and gelatine relief printing are the same.

PAPER.—Use albumenised paper for the purpose you mention.

BRILLIANT.—Try the effect of fuming the paper with ammonia before printing.

GRAPHO.—The size of the country offers an advantage, otherwise there is none.

INQUIRER.—Write to Simpkin & Marshall, Publishers, London, who can supply the book.

X. B. Z. L.—We have not seen the instrument to which you refer, so cannot give an opinion.

GEORGE FINDLAY.—The transferotype of the Eastman Company will serve your purpose well.

P. R.—The image may be reversed by placing a mirror at an angle a little distance in front of the lens.

G. HAUBERNE.—No, the negative is very much under exposed, and no amount of forcing would have brought it up.

ROBERT asks whether a negative washes quickest by being immersed in water face up, face down, or on end.—Face down.

WALTER.—Gelatin with which lampblack is incorporated will answer the purpose. Let there be a trace of glycerine present.

ADOLF JANSSON (Stockholm).—We have no acquaintance with the camera named, and regret that the distance between this office and the agent is too far to conveniently call and see it.

PERPLEXED.—See the article which appeared in the columns of this JOURNAL of November 18, 1881, headed *Practical Hints for Making Carbon Transparencies for Enlargements; Defects and Remedies*.

D. F.—The boiling point of water is both 80° and 100°, as well as 212°. Everything depends upon which of three thermometer scales is employed. The first of the above figures represents Reaumur, the second the Centigrade, and the third the scale of Fahrenheit, the last of which is commonly used in this country.

INVERNESS.—We shall be pleased to see you when you come to London. There is not the slightest objection to the experiments referred to being carried on, even if, as you say, it will take "two or three days." There is plenty of accommodation in it in the shape of bench-room, so you need be at no loss on that score.

DONOTHY.—We suspect that neither of the wide-angle lenses named will possess an advantage over the other as regards the amount of light transmitted to the plate. The including of a wide angle imperatively demands the use of a small diaphragm, this altogether irrespective of the diameter of the lens itself.

MICRO writes: "With a duplex paraffin lamp, metal shade, one and a half inch wicks, and substage condenser, I cannot get sufficient light on the focussing screen when using an eighth of an inch objective. Would an electric lamp be suitable, or what illuminant do you recommend?"—In reply: The electric or limelight.

MCGURK.—1. If it is the back focus that is six and a half inches it ought to answer sufficiently well for taking cabinet heads. The "roughness" of the picture does not depend upon the lens. If it is wanting in sharpness the presumption is that the lens is not good.—2. There are no objections to wide-angle lenses when employed for taking wide-angle pictures.

SOLUBLE.—We learn that an award was really made in that class, but that its announcement was, for some reason of which we are unaware, transferred to another class for a special medal. As you will see, we are not making any descriptive or critical remarks on the pictures in this exhibition. If you would instruct some one to call at this office with a copy for inspection we shall willingly give you our opinion as to its merits.

W. GUTTENBERG says: "I tender my thanks to 'Junius' for suggesting to me the use of papyroxylene in connexion with my time train for use in my magnesium lamp, and intend to experiment with it at my earliest opportunity. I am afraid that it will have the same drawback that gun cotton has in regard to burning with a yellow colour. I shall feel obliged if 'Junius' will inform me if I can procure a sample which will burn free of colour."

T. G. WHAITE writes, in reply to the inquiry of "E. W. M." relative to photographing in Normandy and Brittany: "Brittany has long been my favourite camping-ground, and there is little that is of artistic or antiquarian value that I have not seen. It is famous for Celtic monuments—Menhirs, Dolmens, Cromlechs, Tumuli, Pierres Brulantes, &c. There are also fine shipping pictures to be made at the sardine fishing towns on the coast. Living and travelling can be done cheaply if you know how to go about it."

F. B.—If you had ever attempted to embody in a picture an idea that depended for success wholly upon catching a fleeting expression that must be *natural* to have any value—such idea, in fact, as formed the "point" of many of Roylander's pictures—you would have recognised that "Junius" referred to the rapidity of gelatine plates when he spoke of greater facilities. The "art of concealing art" does not consist in rendering what is supposed to be an expressive smile by an inane grin, as was too often the case in the old days of long exposures.

J. GOLDSWORTHY writes: "Will you kindly tell me (1) the best way to make a good and cheap varnish for ferrotypes that will dry quick and glossy?—2. Also, I have a few photographs in my album that have faded. Could you tell me the best thing I could do to bring them back to their original colour?"—1. A ferrotype varnish to apply cold may be made by dissolving gum dammar in benzole. The proportions to be determined by experiment.—2. Some prints can be restored by removing them from their mounts, and immersing them in a weak solution of bichloride of mercury.

INCORRIGIBLE.—1. This can only be attained by careful study and imitation of the works of others who have acquired a high position as artists.—2. Study a series of articles on lenses in our volume for 1883. You will there find all the particulars necessary.—3. Same as No. 1, applied to landscapes and architecture.—4. Study the excellent series by Mr. Redmond Barrett, which appeared in our volume for 1886, as regards retouching, and in 1887 as applied to colouring.—5. For this and many other departments of photography, study the last edition of Hardwich's *Photography*, published by Churchill. You may also study Robinson's *Pictorial Photography* with great advantage.

LANTERNIST writes: "1. I have two rooms each fourteen feet square, communicating with each other by a central door three feet wide. If I place an optical lantern at the end of one room, and a screen at the end of the other, can a six-foot disc be obtained? or will the diameter of the disc be limited to the three-feet width of the door? The eye takes in a six-foot circle in the position named.—2. Does the Pamphengos light emit too great heat, or a small too disagreeable for drawing-room exhibitions?"—In reply: 1. A six-foot disc will be obtained under the conditions.—2. The Pamphengos lamp will not emit a smell, provided it be kept free from oil on the outside. We have not found the heat excessive.

T. J. H.—The strength of a simple aqueous solution of nitrate of silver may be ascertained with a sufficient degree of accuracy for all practical purposes in photography by means of that form of hydrometer known as the argometer.

F. H. EVANS.—The apparent discrepancy is not difficult of explanation. Contact printing is generally performed, and the highest quality of result can only be obtained by that method with *slow* plates. With such slow plates as gelatino-chloride (for development), collodion emulsion, or some of the specially prepared commercial lantern plates, there is, comparatively speaking, sufficient latitude, especially when we consider that by the employment of a feeble artificial light of tolerably constant force the effect may be graduated to a nicety. Even with very rapid plates and a weak artificial light of known value it is not difficult to expose within bounds; by daylight impossible. The practice of giving three or four times the really necessary exposure, and trusting to development for the rest, is what we wished to condemn in transparency making.

EDDOWES'S Shrewsbury Journal is now issuing a weekly supplement containing a photograph produced by photo-mechanical means of one or other of the fine residences in the surrounding country.

PHOTOGRAPHIC CLUB.—The Bank Holiday outing will be to Twyford station for Sonning, train leaves Paddington at half-past ten. The subject for discussion at the next meeting, April 17, will be *Copying Silver Prints*.

On Thursday, the 4th instant, Mr. G. H. Slight read a paper, *A Retrospect of Photography*, before the East London Natural History and Microscopical Society, Bow and Bromley Institute. Several pictures by various photographic processes were exhibited. At the close the usual discussion ensued.

At the Central Institution of the City and Guilds of London Institute Mr. T. Bolas, F.C.S., is to give a course of six lectures on Photography, commencing on May 8, 1889. The subjects comprise *The Use of Artificial Light in Photography*, *Photo-Mechanical Printing Methods*, and *Direct Contact Printing Methods*.

We have received from Mr. W. England a flash lamp for photographic purposes. The lamp is made of japanned tin. Cotton wool, upon which alcohol is poured, lies in a saucer, through which a short brass tube projects, the other end of the tube being connected with a pneumatic ball by means of a rubber pipe. The magnesium powder is, by means of a hopper supplied with the lamp, poured into the tube and blown out into the centre of the flame by a squeeze on the ball. Connecting pieces are also supplied, by which two or more lamps may be ignited simultaneously. The lamp presents a neat appearance, and is so small as to be easily carried in the pocket.

At the Liberal Club, Glasgow, on the evening of Thursday, April 4, Mr. John Skinner, of the Albion Albuminising Company, was entertained to dinner by many members of the photographic profession and his friends previous to his departure from Glasgow for Sydney, where he intends to reside for the future. On this occasion he was presented with a gold watch, and also a set of handsomely bound volumes, amongst which were the works of Robert Burns. Mr. John Parker made the presentation, and in the most genial of terms paid tribute to Mr. Skinner's worth both as a friend and a business man, and the company's good feelings were heartily expressed, wishing him well in the new field of labour he has chosen. Amongst the gentlemen present were Messrs. Stuart, Parker, Verel, Turnbull, Mason, Stevenson, McKenwick, Lang, Dowie, &c.

ALDERMAN WEBSTER OF WARRINGTON.—With regret we announce the death of Mr. Samuel Mather Webster, a gentleman well known and highly respected in Warrington, and a warm friend of this JOURNAL. Being by profession a chemist, he was intimately conversant with photography in all its branches. He took an active interest in the educational and literary establishments of his native town, and as Hon. Secretary of the Mechanics' Institute he placed it in a financially successful condition. An Alderman of the Warrington Town Council, he was well known and highly respected. His connexion with the Town Council dated from 1847, he being Mayor for three years. He was elected to several responsible offices, and at the time of his death—which occurred on the 3rd instant, at the age of seventy-three—he was Chairman of the School Attendance Committee, Vice-President of the Museum, Library, and Arts Committee. He had a taste for literary work, was for many years local correspondent of a Manchester newspaper, and subsequently became proprietor of the *Warrington Times*. Interested in art work, he was when young a painter of no mean ability. Many of his good qualities are reproduced in his son, Mr. George Watmough Webster, the esteemed and well-known photographer of Chester.

NOTICE.

NEXT week, owing to Good Friday, THE BRITISH JOURNAL OF PHOTOGRAPHY will be published on Thursday, the 18th instant. Consequently all communications and advertisements should be sent one day earlier than usual.

No. 1511. Vol. XXXVI.—APRIL 19, 1889.

PRACTICAL CONSIDERATIONS IN STUDIO BUILDING. IV.

BEFORE dismissing the subject of the pitch of the roof, we would draw attention to one more point to be considered—the rain. We have dealt with the effect of snow, which is only an occasional visitor, but rain has always to be endured and provided against, and the steeper the roof the less the danger of its entering in. Glare from the sun and leakage of rain are the two greatest evils to be provided against by the studio builder. We were once discussing the subject of leaky roofs with a house painter of large experience, and he told us he had never seen the glass roof yet that did not leak at one time or another. Certain precautions, some of which he named, might be taken to reduce the leakage to a minimum; but it was a miracle to find one perfectly water-tight. One of the chief causes of leakage, he stated, was the getting the glass into the frame too quickly. Every bar should have at least two coats of good paint before the glass is put in, and, most important of all, the margins of squares of glass themselves should be painted, on each side, for a breadth of about half an inch, and the paint allowed to set before commencing to glaze. "By this means," he said, "the paint and the putty 'grow together,' and scarcely ever leak, if properly done, even when the outside putty has 'perished.'" And certainly the instances pointed out to us as examples of these precautions seemed to bear out his advice. There are other substances used besides ordinary putty for securing the glass to their frames, and other devices for doing away with putty altogether, but as these could only be suitably treated by those familiar, by practical contact, with their advantages and disadvantages, we will not dwell further upon them.

Taking it for granted that, however great the care taken with the roof, there will always be a possibility of leakage, there are some studios built where from the outset danger of this sort is provided against. One mode is to attach a narrow zinc gutter to the under side of each spar which carries the glass, so that if drops of rain do gain access the gutters will receive them and carry them away. Another plan that has been recommended is to have cut into each spar, in the direction of its length, and before putting it in its place, a narrow groove or channel, into and along which any leakage water will travel. This seems to us an excellent idea, and one that could be put into effect while the studio was in course of erection; there is, indeed, nothing but the question of extra cost to prevent this being carried out in any existing studio, and there are many now in existence where it could be most advantageously done. Our strong advice is to take every pains in making the roof "tight" at first.

But, granted a roof secure against the entry of rain at the outset, periodical re-paintings will be necessary to keep it so; yet the very steps taken to this end may bring about the evil itself. This will happen if the roof be not made of spars sufficiently stout—be they of wood or iron—to withstand the weight of workmen without deflection. How many of the studio roofs now in existence are there which are not defective in this respect! We presume this state of affairs is a survival of wet-collodion days; we can scarcely imagine the deficiency of strength to arise from motives of economy, as the difference in cost between a substantial and safe roof and one of the most flimsy description could only be most trivial. As to the thicker spars obstructing too much light, surely five per cent.—for they could scarcely rob the light to a greater extent—might in these days of quick plates be sacrificed to gain the comfort and convenience of a non-leaky roof! *Verbum sat sapienti.*

Forming part of the great question of roof construction, ventilators must next be considered, made as they are in almost every conceivable shape, from a simple lid in the roof to the most elaborate and complicated structures. It would be futile to indicate a particular form as being the best, for every studio builder has a fad on this subject; but it will be advantageous to point out three considerations sufficiently frequently neglected.

First. The whole principle and practice of ventilation is not summed up in the conception of making an aperture in the highest part of a heated room to let out the heated air, on the principle that, hot air being lighter than cold, it must rise in a given apartment, and make an exit through any aperture there provided. The theory looks pretty, almost perfect, but practice shows that more frequently than not the external air comes in at this particular aperture instead of the inner air going out. Our remarks would be extended to an inconceivable length to discuss this one point alone in all its bearings; it must suffice here for us to draw the attention of the studio builder to the fact that this popular theory is a fallacy when applied without counterbalancing acquaintance with the peculiarities of its application.

Second. There are a large number of ventilators sold which, by means of an outer vane, actuated by wind, work an Archimedeian screw, or otherwise, and literally fan or pump out the air from a room, whatever the conditions of counter-currents or "suction." These ventilators may be very efficient, and often are; but the point to which we call especial attention is, that on the particular occasions when their action is most needed—the close, sultry days, without a breath of air stirring—they utterly fail: they are reduced to the level

of the simple aperture in the roof, and are less efficacious even than it, for the path of exit is obstructed.

Third. A ventilator, of the most efficient kind ever constructed, is of little value unless its sectional area is of considerable size in proportion to the room to be ventilated. It is simply a question of emptying an apartment of given size in a given time, and this all depends, *ceteris paribus*, upon the size of the exit aperture. Clearly, then, to periodically empty the air from a studio—for this and cooling it are convertible terms—the requirements are, exit apertures of sufficient area, and suitably placed as regards counter-currents, and not dependent upon the force of the wind to put them in action. Unfortunately, the solution of the question is more difficult than it appears; it is one upon which doctors differ to a surprising extent.

We can only offer the wish that every one who attempts it may experience the fortune of that one in fifty who only, we believe we should be correct in stating, is successful in effecting this consummation so devoutly to be wished.

THE DEVELOPMENT OF TRANSPARENCIES.

Assuming the plate to have been correctly exposed, according to the general rules laid down in previous articles, there still remains the need for special care in the development of the transparency. As already shown, the positive image differs from that of the negative in that it must represent the highest lights as perfectly bare glass without any trace of deposit, and must also, as it were, condense the various gradations within a far narrower compass. In other words, the transparency must present to the eye a perfectly graded picture commencing from clear glass, the deepest shadows being, however, many degrees removed from perfect opacity, which in this case would lead to heaviness. In fact, for most purposes, but especially in lantern slides, the very deepest shadows should be transparent enough to permit print to be legible through the film when pressed in contact.

These conditions necessitate that the character of the deposit be as nearly perfect as possible, and the development conducted with the greatest skill, following upon what is really the main thing—correct exposure. But though accuracy in exposure is of paramount importance, it is not to be relied upon alone to give perfect results.

We have already shown, in speaking of exposure, that there is less need of minute accuracy when slow plates are used than when the sensitiveness is greater, and precisely the same rule holds good with regard to development. Having previously mentioned collodion plates, we may commence by dealing with these, taking first of all wet collodion.

Many, perhaps most, operators regularly employ the iron developer for transparency work, though others, and we are with them, strongly prefer pyro. We are not now referring to the iron and pyro methods most familiar to the modern photographer, namely, ferrous oxalate and alkaline pyro, but to acidified solutions of ferrous sulphate and pyrogallol. The iron developer, when all things (bath included) are in perfect condition, works with beautiful cleanness and with a much shorter exposure than pyro, hence, no doubt, the preference given to it. But it is not so easy to keep up the conditions which conduce to the highest quality of result in transparency work as it is with pyro, and besides this—which is, perhaps, of

more importance—the “grain” and colour of the image are not so good.

Where iron development is employed, a solution of ferrous sulphate of normal strength—i.e., fifteen grains to the ounce—is perhaps better for general purposes than either more or less. It is better not quite new, though should not be too old; from two or three days to a week, after mixing, will be found the best age. The restraining acid employed will have a great effect upon the colour of the image, and its proportion will rule, not only the clearness of the lights, but also the delicacy of gradation. With the bath in first-rate condition, a minimum proportion of acid will be necessary, but as the silver solution becomes charged with ether and alcohol, and the other consequences of use, the quantity will have to be slightly increased. It must also be borne in mind that a small proportion of acid conduces to softness of gradation; a larger proportion to greater density and more sudden contrasts.

As regards the kind of acid employed, acetic will undoubtedly be found the most generally useful, and when employed alone, from fifteen to twenty minims of the glacial acid will be required to each ounce of fifteen-grain iron solution. Citric, formic, tartaric, nitric, sulphuric, and probably many other acids have been used in conjunction with iron; but for our present purpose there is little need to depart from the one first named. Variations in tone—we are supposing it is not intended to tone artificially—can be produced by substituting a portion of one of the last named acids for a corresponding quantity of acetic, care being taken of course to ascertain their respective equivalent values. Citric acid helps to give a purple black tone; formic yields a brown or reddish tint; tartaric and nitric are principally noticeable for the clean white or metallic surface-colour they give; while if a pure neutral black or grey is desired, sulphuric may be employed. As a rule, the organic acids lend to the production of a black or deep brown colour and great vigour, while the mineral acids give grey or neutral images and greater delicacy.

Variations of the iron solution, such as the substitution of the acetate or nitrate for the sulphate, formerly found much favour, at least for negative work, but for the present purpose do not seem to offer much advantage, their function being rather to yield detail and vigour with a comparatively short exposure than to confer any special benefits of value on a transparency. If, however, it is desired to “prospect” these modified developers, they may be formed by adding to the ordinary solution of ferrous sulphate something less than the equivalent of acetate of soda, or nitrate of barium. The former gives a compound solution containing acetate of iron and sulphate of soda, the latter, if the exact equivalents be employed—which, however, is not advisable—a solution of nitrate of iron alone, as the sulphate of barium formed by double decomposition, being insoluble, separates. These modified solutions of course require to be acidified in the usual manner, but naturally the proportions and nature of the acids may require varying.

Some operators use and recommend other additions to the developer, chiefly of an organic nature—such as sugar, gelatine, and many similar substances; but we have never, even for negative purposes, been able to recognise any real advantage in their use. Gelatine is, perhaps, the best in the form first recommended by Mr. M. Carey Lea—viz., dissolved in sulphuric acid and carefully neutralised. This increases the fineness of the deposit, but must be used very sparingly, as it is a most

powerful restrainer, and, if added in excess, destroys all delicacy of gradation.

If pyrogallic acid be substituted for sulphate of iron, the first and most important difference will be that a very considerable increase will be necessary in the exposure. But, as a counterbalancing advantage, the deposit will be much finer and the colour of the image, as well as its general characteristics, superior. Such at least is the general opinion; but for those who are satisfied with the neutral tint, clear shadows, and somewhat metallic appearance of the iron image, will probably scarcely care to incur the increased exposure.

With the bath in perfect condition, and rather more strongly acidified than is needful for negative work, some of the most beautiful tones can be obtained with pyro development, varying from rich pure black to brown, various shades of purple, or even distinctly red colours. We have in years past, with a well-matured collodion, containing a full proportion of iodide, and all conditions of working satisfactory, produced negatives as well as transparencies of a rich claret or port wine colour by transmitted light, a class of tint that gives a peculiarly rich effect in transparencies, especially for the lantern.

It is scarcely necessary, or, indeed, advisable, to depart from the employment of acetic acid as the restrainer, as the others mentioned in conjunction with iron either offer no advantage or give a decidedly inferior result. Using the pyro and acetic acid in the proportion of one grain of the former to half a drachm of the latter to each ounce of solution, the strength may be varied by dilution in order to suit the class of negative or the character of image required; the stronger solution tends to produce a softer and more harmonious picture, and is better suited for hard, dense negatives, the converse being the case when diluted. If black or purple tones, with a tendency to blue, be desired, then citric acid may be substituted for acetic; this is a much more powerful restrainer, and should only be used in the proportion of about one grain in place of half a drachm of acetic. Or the two acids may be used in combination.

It is usually recommended to mix the pyro and acetic acid solution fresh each day, in which condition it possesses its greatest energy. This may be necessary in ordinary negatives, especially in portrait work, when it is desirable to make the shortest possible exposures, but for transparencies it is not needful; in fact, the solution seems to work absolutely better when a day or two old, and retains its good qualities for several days, certainly over a week.

It would be wrong to leave the subject of the development of wet plates without alluding to the once general practice of silver intensification, or "redevelopment," as it was erroneously termed. This practice came into general use on the introduction of the iron developer, by means of which, and a short exposure, a thin, delicate image was first produced, to be afterwards intensified by the application of a second and more powerfully restrained solution of iron, or of pyro with a little free silver. This plan may be advantageously adopted in conjunction with iron development for transparencies, when it is not desired to lengthen the exposure; and if pyro be employed as the intensifier, though the results are not equal to those obtained with pyro alone, they partake of the same character, and are by most judges preferred to the pure iron tone. Let the pyro be of the strength of one grain to the ounce with half a drachm of acetic or one grain of citric acid, or preferably a combination of the two. Citric gives a colder tone than acetic, but preserves and restrains the solution better. Add a

few drops of plain ten-grain solution of silver nitrate, using more in proportion as a black or cold tone is desired, or it is needful to increase the contrast.

Alkaline and modern forms of development will be separately treated.

"Spring cleaning," and general preparations for the approaching season, appears to be the order of the day amongst professional photographers just now. Already business is decidedly "looking up" in the majority of the leading London establishments. So far as we are aware, there are no very special novelties being introduced at present. The demand for large direct portraiture, however, appears to be rapidly increasing, as we predicted some time ago it would, and, what is more, we learn that it is fully appreciated by the public. In fact, it is a decided commercial success with those who have made it a speciality.

We have always deprecated the taking of life-size portraits direct, and shall continue to do so; but several of those who, during the past few years, have provided themselves with the appliances for doing them are not now employing the apparatus for that purpose. They are, however, putting it to its more legitimate use, namely, for taking portraits on plates of similar dimensions, but including half or three-fourths of the figure only, principally the latter. Three-quarter-length portraits, taken direct on, say, twenty-four-inch plates, with a lens of suitable focal length, when the posing and lighting are good, are very imposing pictures. Such pictures, we are told by those who make a feature of them, are highly approved by their patrons, while they find by experience, if the portrait be taken on a larger scale, it seldom, if ever, proves satisfactory. The reason for this is not far to seek, because, for the larger scale, the lens has to be approached near to the sitter, while, for the smaller, its distance more closely approximates to that from which *cartes* and cabinets are usually taken.

LARGE direct portraiture ought to be highly remunerative to those who make it a speciality. As the necessary apparatus for it is somewhat costly, those who do the excessively low-priced pictures are scarcely likely to adopt it, on account of the outlay. Therefore, it is probable that there will never be that ruinous competition, as regards price, with this class of work that there is with the smaller sizes. Hence, large direct portraiture may be looked forward to as a somewhat select branch of business.

AND the sensitometer numbers given with dry plates of any real value? They ought to be, but there is little question they are often misleading rather than otherwise. It frequently happens that a plate said to be, say, twenty-four by the sensitometer, proves, in practice, to be less sensitive than another mentioned as being twenty-two or even less. Is this discrepancy due to some makers overstating the sensitiveness of their productions, while others under-estimate theirs? Or does it arise from a difference in value of the light used in testing? Or is it due to a variation in the density of the sensitometer screen employed? Or from the whole of these circumstances combined? Recently we saw two sensitometers in use in a plate manufactory, one of which, on careful testing, was fully two numbers in advance of the other. And upon trying the screens side by side on a piece of sensitive paper the difference was even still greater. A standard light and a standard screen are yet *desiderata*. But when they are found they must be employed conscientiously to be of any real value.

THE strong light we have been having of late is making the contents of many showcases look excessively dingy. It is truly surprising how little attention is paid to this subject by many photographers, particularly those in the metropolis. They take immense pains and trouble to get up the specimens in the first instance, but seem to care but little for them afterwards. Some of the *causes* shown at the railway stations are in a woeful plight. When a print fades, surely it is a very easy matter to take another from the negative. The

public exhibition of fading pictures is a decided discredit to photography.

CONSIDERABLE vigilance is being shown just now by the Custom House authorities, with reference to the importation of foreign goods, to see that the Trade Marks Act is complied with. This is all well and good, but we have heard several complaints of the careless way in which it is done. Cases are opened, the paper ruthlessly torn off the packages, and not secured again. Goods which had been carefully packed by the senders are replaced anyhow, so that they can be got back into the case, without consideration as to the damage they may sustain in further transit. In one instance, a large nail, instead of being driven into the wood of the case, was driven inside it, and some distance into a piece of apparatus. Notwithstanding this apparent show of energy on the part of the Customs' officials, there is no question that a great deal of photographic material is being sold in this country which has been made abroad, and which bears no indication whatever that it is not of home production. Particularly is this the case with lenses, chemicals, and photographic stationery.

How much better the majority of landscape photographs would look if the natural sky, as it existed when the picture was taken, could be secured in the negative without sacrificing any of its other good qualities. Particularly would this be the case with the clouds seen at this time of the year, say just after a smart April shower. A large proportion of the clouds printed-in from stock negatives are in no way suited to the pictures for which they are used, and therefore often make it utterly incongruous. This would never be the case if the clouds were secured at the same time as the landscape. Various "dodges," more or less practicable, have from time to time been suggested for attaining this end, but the fact remains that the larger proportion of clouds seen in amateurs' negatives are printed-in from commercial stock negatives.

NOTHING is easier, when taking the landscape, and there are good clouds at the time, without altering the position of the camera, except, perhaps, raising the front a bit, to take a second negative, exposing it specially for the sky. By this means an excellent cloud negative, suitable to the landscape, would be secured, which could be utilised without any troublesome masking or blocking-out, because the two negatives would be in duplicate as regards subject. It may be argued that this would often involve the use of two plates for one picture. This is true, but then three or four pictures of exceptional excellence are far preferable to half a dozen of little merit.

IN nine cases out of ten, when clouds are printed-in to a stereoscopic picture from a second negative they are a total failure when seen in the stereoscope. If, however, the plan suggested above be adopted, the clouds will always be in harmony with the picture, and will also possess the proper stereoscopic effect when viewed in the instrument.

A LETTER from a correspondent, in our last issue, on "sweating" in photography, directs attention to the ill-effects of competition namely, the large amount of work that must necessarily be done for a very little pay. However, the sweating system in photography has not yet assumed such proportions as to call for legislative interference, as our correspondent suggests. That sweating is carried on there is no doubt, otherwise photographs could not be produced at the ridiculously low prices they sometimes are. Long hours and small wages must largely rule in some quarters, but not, we hope, in good-class establishments.

IN no branches of the art is sweating carried on to the extent it is in the production of the cheap opal pictures, to which we have before referred, and in the colouring and finishing of photographs. The latter often passes through three or four hands before it reaches the customer. In the lower grades of this branch of work, such as the tinting of publication portraits, and the colouring of cheap opals, the prices paid to those who actually do the work are, we are told, so ridiculously small, that it is almost a wonder that people can be found to under-

take it at all. However, we are given to understand that a large proportion of this work is done by young ladies of the middle class, who do it to obtain a little extra "pin money," and not really as a means of livelihood. This, however, makes the matter no better—indeed, it makes it worse—for the needy ones who have to depend upon their labour for the necessities of life.

THE SIMILARITY OF ACTION OF DIFFERENT DEVELOPERS.

THE observation made by Mr. Cadett in the course of his paper on *Development*, given before the Camera Club, to the effect that all the different developers he had tried exhibited precisely the same power in rendering detail, though perhaps at first sight rather startling, must, I think, commend itself to the more careful and observant of manipulators. Presuming, of course, that the best use is made of each different combination, that is to say, that the utmost detail is got that the developer is capable of bringing out, I have never found that there was anything really appreciable to choose between any of the wide range of mixtures possible. But when it comes to density, gradation, and *printing value*, the case is very different. For instance, who that has experimented with developers, using the sensitometer, has not discovered that with the same class of film—i.e., a large plate, or sheet of paper cut into small sections—the same number will be got out invariably by any developer if it be applied for a sufficient length of time? I do not mean to say that by a sufficiently long application the whole range of numbers will be compassed, because such is certainly not the case; but a certain point is reached beyond which the most energetic solution will not act further, however long permitted to act, though the slower workers will gradually reach it allowed. But the difference in the appearance of the developed images will be as great as, or greater than, the variation in the time occupied, both in vigour and in the "picking out" of grade from grade. Perhaps some unthinking reader may ask then, "Why vary the developer at all?" or, "Why not use a 'one solution' developer, instead of condemning such as unscientific?" Well, the reply is very simple. In actual practical development, the action of the developer is rarely, if ever, carried to its utmost limit; not even in the case of "instantaneous" exposures. The science of development consists in so modifying the character of the solution to suit the time of exposure, that it shall produce the result desired before it has reached the point of exhaustion. If this were not so there would be no such thing as "latitude." We should have to expose with the strictest accuracy, and then the developer might be allowed to act for any length of time. But what would be the consequence of leaving a plate that had received a "normal" exposure to develop, say, all night? Why simply that though no more detail, properly so-called, would be produced than if the action had been arrested at the right time, the gradations of light and shadow would be utterly lost, the density of the image be infinitely too great, and most probably a hopeless veil of fog thrown over the whole by the abnormal action of the solution.

The fact pointed out by Mr. Cadett is, however, I think, strongly in favour of the theory of Mr. Payne Jennings, also alluded to in the same paper, that, however brief the exposure may be, the image is completely formed, if it were only in our power—which it is not, with our present knowledge—to bring it out. But considering the advances made in late years in this direction, there is no knowing how soon the necessary knowledge may dawn upon us.

Another remark of Mr. Cadett's will be re-echoed by many good workers, and perhaps cavilled at by others equally good, namely, that the more non-actinic the colour of the negative the greater will be the delicacy of its gradations. There can be no dispute on the question of the relative prettiness of negatives developed with and without sulphite of soda, nor of the difference in the rapidity of printing; but there are many who cling to the idea that the old pyro-stained images give the better prints, and still more who favour sulphite, because of the "wet-plate character" it gives to the negative.

It scarcely requires argument that a dense image offers a better chance of securing a wide range of delicate gradations—a more extended "gamut" as it has been called—than a comparatively thin one. But the scale must start from "zero," and the range of grada-

tions will be only limited by the length of the scale. The scale should extend, in fact, from "clear glass" to "opacity," the two limits beyond which it is impossible to pass. The "backers" of pyro-stained negatives forget that they necessarily shorten their scale by having no "zero," while the lovers of sulphite, on the other hand, overlook the fact that in many—perhaps the majority of instances—they stop many degrees short of opacity, and consequently curtail the scale at the other end. Sulphite or ferrous oxalate developed negatives resemble a wet plate in colour more than in gradation. It is not the colour, but the gradation of collodion negatives that cause them or their recollection to remain so firmly fixed in the remembrance of the old votaries of the art. Some of the finest and most delicate, as well as vigorous collodion negatives ever produced are as far removed in colour from the neutral black of ferrous oxalate or sulpho-pyrogallol as the most deeply pyro-stained gelatine, or even farther. Mr. Cadett's dictum remains correct.

B. W. C.

ALBUMINO-BROMIDE PAPER.

SOME time ago I noticed the mention in your columns of the possibility of utilising, as a makeshift for enlarging or similar purposes, ordinary ready-sensitised albumen paper treated with solution of a soluble bromide in order to convert the silver chloride into bromide. As I have frequently, during many years past, availed myself of this method of extemporising a moderately rapid paper for printing by development, and found it both useful and reliable, I think that with our modern facilities, especially in development, it may be fairly removed from the category of "makeshifts," and classed as a really practical help. I say this more especially because it is not only as a substitute, in cases of emergency, for the now generally used bromogelatine paper that it offers itself; because even in the chance cases where the supply of such paper should run out, the results obtained with the substitute are scarcely likely from their different character to give satisfaction. But I aver that a distinct and characteristic style of picture is obtainable by development upon bromised albumen paper which gives it a *raison d'être* entirely its own.

Many who have so far changed their opinions as to favour the now popular black or platinotype tones have scarcely yet lost their fancy for the albumen surface; and certainly for small work such tones, combined with the finish of albumenised paper, produce a marvellously pretty effect, while for large work if the gloss be an objection it may be dispensed with, and the peculiar and distinctive character of the picture retained.

My own experience with ready-sensitised paper has been comparatively—or I may say very—limited, as I have only tried that modification of the plan recently, and since I came across the mention in your pages. My practice has been to sensitise my own paper, and it has been with such that I have invariably done my work. There is everything to recommend this course where regular work is to be done by the process, since, when it is perfectly well known under what condition the chloride paper has been prepared and sensitised, there is a better chance of securing the finest result in converting it to its new purpose. In fact, when it is known what strength of sensitising bath has been employed, some idea may be formed of what strength of bromide solution will give the best result.

So far as my experience with commercial sensitised paper has gone, I have not found it to give such generally satisfactory results as the home-prepared article, probably because, being comparatively devoid of free silver nitrate, the chloride present is barely sufficient to meet the requirements of a developed print. Still, very good work may be done, especially in small sizes, when delicacy rather than vigour is the quality to be sought. In ready-sensitised paper I have obtained the best success with a weak bromide bath long applied—say, fifteen grains of bromide of potassium to the ounce of water and allowed to act for not less than a quarter of an hour. The paper is simply floated on the "converting" bath in the same manner as in sensitising, the surplus solution removed, and the sheet hung up to dry.

When the paper is of my own sensitising, I regulate the strength of the converting bath to that of the silver bath, using about one-third the strength of bromide (of either potassium or ammonia) as compared with silver. For instance, if the silver bath is sixty grains, I find a twenty-grain bromide bath ample. If it be stronger than

this there is a danger of the chloride or bromide of silver being dissolved, and the paper robbed of its sensitive material. To avoid this at all times, and to obviate the necessity for particular care in the time of floating, I saturate the bromide bath with silver by shaking it up with a small quantity of freshly precipitated silver bromide, or, what answers equally well, by adding a few drops of solution of silver nitrate and filtering before use.

If the paper is sensitised for ordinary printing, the surplus solution will be removed from the surface by means of a glass rod or by drawing the sheet over the side of the dish; in which case, especially after drying, the albumen surface will be quite ready for floating upon the converting bath. But if the surplus silver be not thus removed, or if the sheet be removed directly from the silver to the bromide bath, unsightly markings will occur on the surface from the conversion of the excess of silver into a scum-like deposit of bromide. To avoid this when specially silvering the paper, I float for a rather shorter time than I should for ordinary printing, and allow the sheet to hang for ten minutes or a quarter of an hour before placing on the bromide bath, during which time the excess of nitrate will have been converted into chloride, or absorbed into the paper.

For large work, or when the albumen gloss is undesirable, I float the reverse side of the sheet, which then becomes the sensitive surface. It is useless to print on the back of the paper when the front is sensitised, as the picture is then formed mainly in the paper, is but partially visible on the front, and scarcely at all at the back, but shows well as a transparency. When, however, the back is placed in contact with the sensitising solution, the chlorides contained in the albumen layer find their way through to meet the silver, and the result is the formation of a bold, strong, and rich-coloured image, when the reverse side of the paper is presented to the light.

A very noticeable increase of sensitiveness is attained by a somewhat roundabout method. After sensitising, the sheet is allowed to drip for a few minutes, and is then floated on a weak solution of carbonate of soda—five grains to the ounce—which converts the excess of nitrate into carbonate of silver. If the carbonate be used much stronger there will be danger of injuring the albumen film. After again hanging for a minute or two, or removing the excess of liquid from the surface, the sheet is transferred to the converting bath, which should be of bromide of ammonium; this, in converting the chloride and carbonate of silver, forms by double decomposition a small trace of carbonate of ammonia, which acts as the accelerator.

The floating on the converting bath should last about ten minutes, but no harm is done if it extend longer. On no account immerse the paper at this stage, or the image will be made to penetrate into the body of the paper, which, however useful it may be for negative purposes, is not to be desired when positives are in question. When the conversion of the chloride is complete, then immersion may be resorted to, and is, indeed, desirable in washing out the excess of soluble bromide; the process is thus hastened, and no possible harm can accrue from the freest and most liberal use of water.

Upon the thoroughness of the washing, and the consequent removal of as much as possible of the free bromide, will depend in a great measure the sensitiveness of the paper. Several sheets may be worked in the same dish or vessel, and if a constant stream of water be kept up from half an hour to an hour it will be ample, after which the sheets may be "blotted off" singly with clean bibulous paper, and hung up to dry. It may be observed that when thoroughly washed such paper should keep indefinitely, and is infinitely less liable to injury than gelatine paper from any cause whatsoever, neither heat nor damp exercising any ill effect.

As regards sensitiveness, I class paper prepared in this manner as about equal to, or perhaps a little slower than, Alpha paper, when the same development is adopted; but a good deal will depend upon circumstances. If greater sensitiveness is desired, the paper may be soaked for a few minutes in a weak solution of carbonate of ammonia, though this is dangerous if ferrous oxalate is to be used as the developer, unless a very thorough washing intervene. The developing solution itself may be warmed in cases of slight under exposure, but the practice is not to be recommended, as it tends to degrade the lights of the picture.

Of the different methods of development I must speak in a future article, simply saying here that alkaline pyro, hydroquinone, and

ferrous oxalate are equally available, while those who remember "old times," and do not object to the lengthened exposure necessary, may use "acid pyro," or even gallic acid.

ERNEST GRAHAM.

ECHOES.

In last week's issue, Mr. W. Guttenberg asks me a question with regard to papyroxylene, which I am afraid I cannot answer as satisfactorily as he might wish. The yellowness of the flame is quite as pronounced as in the case of ordinary gun cotton, or it may be more so, for it varies with the rapidity of combustion; and this again, in the unconfined state, depends upon the physical character of the explosive, and not wholly upon its degree of nitration.

A perfectly dry and well "pulled-out" tuft of gun cotton will flash off with a degree of rapidity that varies, of course more or less, with its chemical composition, but is always sufficiently rapid to deserve the term of "flash." Papyroxylene, on the other hand, may be made of the highest degree of "explosiveness," but yet which will burn with about the rapidity (?) of a slow match, simply because it is so thick and compact in its physical character. For instance, a sample I have made from thin Swedish filter paper, with equal parts of undiluted acids, at the temperature of 62°, is, in consequence of the parchmientising action of the sulphuric acid, as thick as, or thicker, than stout cartridge paper. When cut into strips and laid in a continuous "train" on the floor, and creased so as to prevent as much as possible contact with the cold surface, it burns only at the rate of about an inch in a second. But the combustion of any magnesium powder spread upon it is complete if it be but slow, and for prolonged exposures I should think it would answer well.

In order to make a rapidly flashing sample, it would be necessary to employ the thinnest tissue paper and a very much larger proportion of nitric acid, in order to prevent the parchmientising action, and to keep the product as thin and light as possible. If Mr. Guttenberg would like to try samples of the two sorts, I shall be pleased to forward him some through the Editor.

With respect to the yellow colour, however, I do not think it can be considered detrimental—as I assume Mr. Guttenberg regards it—on account of any supposed slowing effect it may have on the magnesium. Granted that a certain proportion of useless rays are mixed with the chemically active magnesium, I question whether the value of the latter is thereby reduced. It is not as if the light were passed through a non-actinic medium which robbed it of the whole or a greater part of its activity; on the contrary, the active rays are present in vastly preponderating proportion, and fully capable, so far as I can see, of exerting their full inference. It is a case, in fact, of white light *plus* a small proportion of yellow, and not, as would otherwise appear, white light *minus* a portion of its violet and blue.

If the admixture of coloured with white light robbed the latter of any of its chemical activity, it would seem that a very considerable leakage of daylight might be permitted into the "dark room," especially when ruby light is employed. Such is not the case however, in spite of the, I may say, established reversing action of the red rays, which one would imagine would suffice to "kill" any slight glimpses of white light that might filter in. Not so however, for the most minute traces of white light seem capable of exerting their full power for evil, as most photographers must have discovered.

The battle of hydroquinone goes on right merrily, and in this, as in almost anything—especially things photographic—it seems possible to elicit opinions and ideas of the most opposite character. As regards the value of the substance as a developer this is not to be wondered at, since, all the world over, "different people have different opinions; some like apples, while some like 'inyns!'" But when it comes to the chemical composition of the material, one would expect a somewhat closer agreement; for while chemistry is not so exact a science as mathematics, it is practically so within limits.

But here we have one statement contradicted by another with such plainness and directness, that one begins to wonder whether chemistry is not, after all, about as much guess work as phrenology or palmistry. Still, where differences exist and have to be written about in scientific matters, it is incumbent on the disputants to express themselves with-

out personalities or without the imputation of unworthy motives. I was sorry to see, in a letter in the correspondence columns a fortnight ago, a suggestion that certain figures given in a paper read semi-privately by an entirely disinterested party were—well, practically, "cooked," to suit a certain hypothesis. That, I venture to say, is stepping beyond reasonable bounds; and the further suggestion, that most accurate workers are usually the most modest, is unnecessarily and unpleasantly critical, but suggests that if the accuracy of every worker were gauged by his apparent modesty, even the writer of the letter I quote from might find himself not placed in a high rank as regards reliability.

I am willing to believe the remarks were made in joke, for it is always difficult to express jocoseness in "black and white," especially in conjunction with scientific matters, and it is always dangerous to "chaff" in writing. Some years ago I mortally offended a dear friend by some facetious (?) remarks clumsily written, and to quote Oliver Wendell Holmes—

"And since, I never dare to write
As funny as I can."

I am, perhaps, laying myself open to the charge of poking my nose into business that is no concern of mine; but my function, it must be borne in mind, is to be critical, though I hope—as I endeavour—to keep within the proper lines. What I have written is in defence of, and a protest against, respectively, two perfect strangers to me, my only excuse for interference being that they have become public characters in the pages of THE BRITISH JOURNAL OF PHOTOGRAPHY.

JUNUS.

CRYSTAL PALACE INTERNATIONAL PHOTOGRAPHIC EXHIBITION.—V.

By far the least satisfactory things to submit to public show in a photographic exhibition are lenses. Speaking generally, they are all kept in well locked-up cases, thereby acceding to the general wish of the general public to be delivered from temptation, for in this class of wares it is emphatically a case of precious goods made up in small parcels. Even if submitted to examination, one can, at least, say that they are well finished, very pretty, and very diversified as regards dimensions and application; but in the absence of a camera with a ground glass, on which to see their performance, this is all that it is possible to say. For their excellence as efficient working tools for the photographer we fall back upon the reputations of the respective makers. With this by way of exordium, we proceed to state that—

Ross & Co. (112, New Bond-street, W.) exhibit portrait and view lenses, any, or all, of which will sustain the well-earned high reputation of this firm. Many of the latter of these are adapted to fit one flange, an advantage greater by far than appears on the surface, and on which, did space permit, we could dilate at great length. A special novelty consists in their New Patent Concentric Symmetrical Lens, concerning the nature of which no definite public announcement has yet been made. A camera exhibited by this firm possesses the very acme of portability and neatness, but as it was described in these columns only a short time since (page 58), we refer the reader to that description for full particulars. Among their exhibits also are a full-sized skeleton finder attached to a camera, an enlarging lantern, and chemical cases.

The showcase of J. H. Dallmeyer (25, Newman-street, W.) is quite representative of the lenses manufactured by this well-known firm, being replete in every respect. One noteworthy exhibit in it consists of an iris diaphragmatic shutter affixed to a large lens, containing a variety of ingenious adjustments of a chromometric nature. Cameras and finders are also exhibited by Mr. Dallmeyer.

Very varied, too, are the lenticular exhibits of William Wray, Highgate, who, during the past twelve months, has brought out several new productions, both as entirely original or as further developments of works formerly executed by them. Among these is a single landscape lens composed of three components, different (so far as we learn) in arrangement from anything hitherto effected in single-triple combinations. This firm also exhibits a new shutter, time and instantaneous, entitled the "Caldwell."

The Docwra Triple Lantern, which was last year exhibited by W. C. Hughes, Kingsland, E., and for which he obtained the medal, is this year present in an improved form, and it comes attended by numerous other lanterns of an allied nature, and with many appliances for this now popular instrument. These embrace Bijou and other enlarging lanterns having rectangular condensers, oxyhydrogen

microscopes, polariscopes limelight burners, long-focus objectives, and the well-known Gilchrist science lantern for demonstrating chemical experiments. One useful novelty we are glad to see amongst Mr. Hughes's exhibits—it is a metallic binding for lantern slides, somewhat on the same principle as the brass "preserve" of old collodion positive days, but modified, of course, to suit this special requirement. Those who are annoyed by the tearing of the paper bindings of slides that are in constant use will find in this metallic binding something that will put a termination to their troubles.

Could a general representative exhibition of photographic apparatus be complete if J. Lancaster & Son, of Birmingham, were absent? Surely not. The great populariser of amateur "sets," Mr. W. J. Lancaster, was present at the opening of the exhibition, attended by a staff of assistants, busily employed in getting his exceedingly varied and large stock displayed in an adequate manner. In cameras there are the "Instantograph," "Le Merveilleux," and "Le Meritoir," all of the 1889 patterns, the "International," the "Ladies," the "Detective," the "Stereo-Instantograph" (a move in a decidedly excellent direction), the "Special," the "Waistcoat Pocket," and others. Then in lenses there are Portraits and Rectigraphs, the latter in several forms and possessing several capabilities, being both rapid, wide, and narrow angle, together with single landscape achromatic combinations. Equally varied are the shutters shown by this firm of manufacturers, whose exhibits include, also, lamps of various forms, print and negative washers, cases for cameras, and numerous other objects of utility.

A large supply of photographic appurtenances are to be found on the stand of Mr. William Tylar (Birmingham), amongst them being zinc-plate boxes, dark-room lamps, with different shades of ruby glass, pulp trays, trays provided with plate lifters, washing racks which fold in small compass, rockers, cameras, stands, burnishers, and, in fact, everything that is necessary for both professional and amateur. Mr. Tylar has recently brought out a film clip, by which one end of a film is securely held whilst being developed. The jaws of the clip are held together by means of a spring, which also forms the handle, pressure upon which will cause it to release its hold. Vignette clips, also recently brought before the public by this house, also fill a long-felt want, as by means of these a sheet of cardboard, which has been previously cut in form for a vignette, can be instantly clamped to the printing frame. These clamps, though very simple in construction, are very effective.

J. F. Shew & Co., besides their well-known stock of cameras and stands of every description, exhibit their Eclipse Changing Back, by which a dozen plates can be changed for exposure, the changing box being the dark slide itself; an ingenious clip, by means of which a camera may be readily attached to the stem of a tree or fence, in place of a stand. The clip, when folded up, occupies a small space.

A fine display of transparencies is exhibited by the Paget Prize Plate Company. The stand of transparencies, being illuminated at right by means of the electric light, has attracted no small attention from the visitors to the Palace.

R. W. Thomas & Co. have an exhibit of their well-known plates and chemicals, specimens obtained by the use of their plates, and the new detective camera of J. B. B. Wellington.

A number of general exhibits by various parties are made on one or two stands under the charge of Mr. E. N. Smart, of Clapham Junction, there being specimens of work done in plates manufactured by F. W. Vétel; cameras, by W. R. Baker; an automatic print holder, by Horace O. Oliver; cameras of various sizes and styles, by Rendall & Co.; albums and mounts, by E. Fox & Co.; burnishers, by Whitaker; camera gun, by J. Lenton Berry; flash lamps, by A. James; fancy and plush frames, by O. Siebel & Co.; specimens of pictures taken on plates made by B. J. Edwards & Co.; a dark slide, by T. J. Rickwood; and several others.

W. Morley has an attractive show of cameras, stands, and lenses. Mr. Morley, as a dealer, occupies the high vantage ground of being a good practical photographer, and knows just what is suited to public taste.

The Platinotype Company exhibit some fine specimens, of various dimensions, taken by the Platinotype process.

The Eastman Dry Plate and Film Company (London) have a goodly show of all, or mostly all, of those appliances with which their names are so well associated. Here are the mammoth cameras of the Scovill manufacture and their well-known Kodak. McKellen's cameras are shown, together with enlarging and other cameras; also roll holders, enlarging easels, bromide and transferotype paper, stripping films, Zschneider's self-binding mounts, film carrier for cut sheets, quadruplex enamellers, retouching sets, washing apparatus, transparency frames with etched glass (by the

way, is it not now a rather old American invention about which some of our correspondents are having an unpleasantness amongst themselves?), and printing frames. This firm also exhibits the centrifugal separating machines of Watson, Laidlaw, & Co., which

Fig. 25.

for the small user has assumed a more convenient form than when it was last figured and described by us, as will be seen from the specimen shown in the above cut. The speed attained is very high.

The London Stereoscopic Company's exhibit comprises complete outfits for beginners and students, chemical chests, detective and

Fig. 26.

hand cameras, vest or secret cameras, also an ingenious form of camera, the appearance of which is similar to a book (Fig. 26). Portable or lawn studios are also shown, "Black band" and other lenses are also exhibited, these lenses being fitted with an iris diaphragm.

Plates of all degrees of rapidity are also prominent in their display.

Fig. 27.

Amongst some of the novelties by this firm is a reversing tripod top, enabling a camera to be instantly turned on its side in order to take

vertical pictures. These tops can be adapted to any stand. Also a compact form of hand stereoscopic camera, the chief points claimed being extreme portability and compactness combined with utility. The camera when packed contains lenses, three double dark slides, and instantaneous shutter. As will be seen by the cut, this camera is furnished with a handle to facilitate carrying. Portable printing frames, burnishers, lamps, photographs, &c., are all to be found amongst the exhibits of this well-known firm.

Lanterns—biennial and triple—are exhibited by J. H. Steward. His "Perfect" lantern has a fine appearance, and is fitted with various objectives of different foci, telescopic fronts, registering stages, double slide, curtain shutter, and all the minutiae with which a lantern of a high quality can be furnished. He also shows an incandescent electric optical lamp of one hundred candle power, which is constructed in such a manner that it is claimed that the area of light is concentrated so that all the rays are available for projection. An ample supply of gas regulators, cylinders, gas testers, and complete photographic sets, are also to be found among the exhibits of this well-known firm.

Since writing the foregoing, the Exhibition is closed. Taken all in all, there was undoubtedly a finer and larger display of photographic apparatus than has been known to have been seen elsewhere, the newest and best of everything having been there displayed.

AN EASY AND ECONOMICAL METHOD OF MAKING LANTERN PLATES.

A FEW weeks ago I was showing our Editor some lantern plates that I had produced by a new formula which I have lately worked out. He was so pleased with them that he asked me if I would publish a full description of how I made them.

I headed my communication as above and began as follows:—"Many of your readers will no doubt say that it is not worth the trouble to prepare one's own plates when they can be bought at a shilling per dozen." Then I came to a full stop in more senses than one, and I asked myself if it was worth while going on any further.

On thinking over the matter since, I have come to the conclusion that, as many of your readers have joined the ranks of amateur photographers since the days when the subject of the preparation of dry plates was one which occupied a large space in the columns of our journals, it will be necessary for me to first explain fully the points connected with the subject to enable your younger readers to decide, each for himself, as to whether it will be advisable for him to take the trouble of preparing plates for his own use.

First, as to the cost. I find that with the emulsion, the formula for making which I am about to publish, I can coat one hundred and twenty plates $3\frac{1}{2} \times 3\frac{1}{2}$ at a cost for material of *fivepence*. A friend of mine told me lately that he expects me to show some plates next which had been coated with some gelatine and bromide of potassium, and then rubbed with a shilling over the surface. If it were possible to produce plates at all or of a better quality by that method, I do not see any objection in doing that—besides, it would reduce the cost of production.

But the question of quality is of far more importance than that of price, and if I found that I could gain anything in quality by using more silver in the emulsion, I would most certainly do so; but I have conclusively proved to my own mind that the quality of the plate depends upon the formation of the silver haloid during the preparation of the emulsion far more than upon the amount of silver in the film, and that after one has obtained a film giving sufficient density, that every atom of silver put into it beyond that is not only wasted but is really injurious, on account of the additional silver blocking up the image, especially in the shadows.

We may say then that if we cut up our waste negatives into plates three and a quarter inches square, and clean off the old films, that one halfpenny per dozen would represent the total cost of the plates. If any one is so fortunate as to have no waste negatives, glass cut to that size can be purchased at 3s. 6d. per gross, and I have no doubt that if there were any demand for it, the dealers would soon lower the price to 2s. 6d. per gross.

It must be clearly understood that, because these plates can be prepared for such a low price, it does not follow for one moment that at present the cost of material to the plate makers is no more than that, or that they use anything approaching such a small amount of silver in their films as I do; indeed, I am very doubtful whether a formula suitable for the preparation of, say, ten or twenty ounces of

emulsion, would be suitable for the same when made in quantities of ten or twenty gallons, and I can quite believe that several plate makers are working with a very small margin of profit in supplying quarter-plates at a shilling per dozen.

During a long series of experiments extending over the past seven or eight years, to try to discover the laws which govern the primary formation of the silver haloid in an emulsion, and the relation it bears to the production of the latent image and its development, I have noted many points which would require pages of this JOURNAL to describe; but I think I may summarise them as far as this branch of the subject is concerned, by saying that I feel convinced that for small plates, such as lantern slides, to obtain the best results it is absolutely necessary for the particles of silver bromide to be in as fine a state of sub-division as possible, and that these particles must be kept sufficiently apart by the vehicle holding them in suspension, that the developer is only able to reduce them to the extent that they are acted upon by light.

Perhaps I can explain my meaning better if we suppose that a developed gelatine film containing the reduced particles of silver in a very coarse state of division (such as in a very rapid gelatine plate) is represented by a number of billiard balls embedded in a large block of ice: on looking through that block of ice the billiard balls would have shut off a certain amount of transmitted light. (With a negative we would say that it had a certain degree of density through the particles of silver blocking out the light in a similar manner.)

Next, we will represent a film containing the silver particles in a very fine state of division (such as in a collodio-bromide plate) by a similar block of ice, in which is embedded a vast number of small marbles.

We can readily understand that as these marbles would lie so much closer together, a much less quantity in bulk would block out the same amount of light passing through the lump of ice than in the case of the billiard balls. I think this will clearly explain how it is that with only about a *quarter of a grain of silver in a plate three and a quarter inches square* I can obtain greater density than often is obtained on a plate containing six or seven times that amount of silver when prepared by the ordinary method.

This will also explain my reason for using such a small quantity of silver in the film, especially for lantern plates which are only exposed to a light the strength of which can be controlled. If I were to use the same amount of silver in a fine state of division as is used when in a coarse state, I should obtain a great deal too much density, and lose all that brilliancy in the shadows so necessary for a good lantern plate.

There is another very important gain in using a small amount of silver in a very fine state of division, and that is for a lantern slide we require the image to be of the finest possible detail and range of tone. To go back to the simile of the block of ice and the billiard balls, as representing coarse particles of silver bromide in the film. If a pencil of light were to strike a small point on one of these balls or particles, the whole of it would be reduced by the developer (as silver bromide cannot exist in contact with freshly reduced silver), and in consequence there would be a blocking up of detail, because more silver would be reduced than was actually acted upon by light.

But if the same pencil of light struck one of the marbles in a group the same size as the billiard ball, that only would be reduced by the developer, the other marbles (*i.e.*, fine particles) being protected from the reducing action of the developer by the gelatine surrounding them.

I think we shall now be able to understand why we are able to get so much better results with a collodio-bromide plate in which the silver haloid is very slowly formed in an extremely fine state of division during the preparation of the emulsion when compared with a transparency produced on an ordinary gelatine plate, and it also gives us a clue as to how to prepare a gelatine emulsion able to equal the former in quality.

The next point that an amateur would require to know is, to what extent would home-made plate making interfere with the arrangements of an ordinary household?

If one can obtain the use of a room with a table or bench in it for two or three hours of an evening, and be allowed to cover up the fireplace for a day or so, that will be the sole amount of inconvenience to which the "powers that be" will be put. As to the plant required, any one who has a few tools, and has a slight idea how to use them, can easily make the form of drying box which I shall describe. This would come in useful if he afterwards decided to make his own plates for the camera, if only to the extent of recoating his spoilt and useless negatives—articles of which amateurs, as a rule, have a good supply.

The last question is, "Can an ordinary photographic amateur with

little chemical knowledge prepare satisfactory plates?" I say most decidedly, "Yes."

I have never quite been able to understand why the halo of mystery and awe at present surrounding the process of plate making is so generally existent in the minds of photographers.

When we think of the vastly greater difficulties in the old collodion dry plate day, which the amateurs of that time successfully overcame, and when we note the great amount of energy on the part of amateurs of the present day in trying every possible variety of apparatus, instantaneous shutter, developer, &c.—the more complicated it is the more greedily it is pounced upon—one wonders how it is that this, I might say in many cases wasted, energy is not directed to plate making to a greater extent than it is.

To prepare very rapid plates with any degree of certainty requires a great amount of care and experience, and until that amount of experience is gained, I would not advise any one to attempt to make rapid plates. But there is no great difficulty in preparing a good slow plate, which is just the thing for landscape work during the summer months; and if your readers who think of giving plate making a trial will first try their hands at preparing small slow plates, such as for lantern slides, they will afterwards be able to coat larger plates with a more rapid emulsion with some certainty of success.

It must be remembered that those who, eight or ten years ago, attempted plate making on a small scale, and gave it up, worked under very different conditions.

In the first place, the great thing tried for then was extreme rapidity, without any certain knowledge of the causes which produced that rapidity. Then again, at that time, little was known or even guessed as to the part that the gelatine played in producing the failures met with. Now the gelatine makers know much better how to produce an article suitable for photographic work, and I am quite convinced that it is to the sample of gelatine used that nine-tenths of the difficulties met with in preparing rapid plates are really due.

In my next communication I purpose to give, in as simple a manner as possible, a full description of the articles required and the method of making the emulsion I have spoken of. Before doing so, however, I thought it better to write the above, so that any one can answer for himself the question, "Is it worth the trouble?"

HERBERT S. STARNES.

SCIENCE AND ART.*

We shall now endeavour to discuss briefly how our remarks apply to photography. Any student of photographic literature is well aware that numerous papers are constantly being published by persons who evidently are not aware of this radical distinction between Science and Art.

The student will see it constantly advocated that every detail of a picture should be impartially rendered with a biting accuracy, and this in all cases—this biting sharpness being, as Mr. T. F. Goolall, the landscape painter, says, "Quite fatal from the artistic standpoint." If the rendering were always given sharply, the work would belong to the category of topography or the knowledge of places—that is, Science. To continue, the student will find directions for producing an unvarying quality in his negatives. He will be told how negatives of low-toned effects may be made to give prints like negatives taken in bright sunshine; in short, he will find that these writers have a scientific ideal, a sort of standard negative by which to gauge all others. And if these writers are questioned, the student will find the standard negative is one in which all detail is rendered with microscopic sharpness, and one taken evidently in the brightest sunshine. We once heard it seriously proposed that there should be some sort of standard lantern slide. My allotted time is too brief to give further examples. Suffice it to say, that this unvarying standard negative would be admirable if Nature were unvarying in her moods; until that comes to pass there must be as much variety in negatives as there are different moods in Nature.

It is, we think, because of the confusion of the aims of Science and Art that the majority of photographs fail either as scientific records or works of art. It would be easy to point out how the majority are false scientifically, and easier still to show how they are simply devoid of all artistic qualities. They serve, however, as many have served, as topographical records of faces, buildings, and landscapes, but often incorrect records at that. It is curious and interesting to observe that such work always requires a name. It is a photograph of Mr. Jones, of Mont Blanc, or of the Houses of Parliament. On the other hand, a work of art really requires no name—it speaks for itself. It has no burning desire to be christened, for its aim is to give the beholder aesthetic pleasure, and not to add to his knowledge or the science of places—i.e., geography. The work of Art, it cannot too often be repeated, appeals to man's emotional side; it has no wish to add to his knowledge—to his Science. On the other hand, topographical works appeal to his

intellectual side; they refresh his memory of absent persons or landscapes, or they add to his knowledge. To anticipate criticism, I should like to say that of course in all mental processes the intellectual and emotional factors are inseparable, yet the one is always subordinated to the other. The emotional is subordinate when we are solving a mathematical problem, the intellectual is decidedly subordinate when we are making love. Psychologists have analysed to a remarkable extent the intellectual phenomena, but the knowledge of the components of the sentiments or the emotional phenomena is, as Mr. Herbert Spencer says, "altogether vague in its outlines, and has a structure which continues indistinct even under the most patient introspection. Dim traces of different components may be discerned; but the limitations, both of the whole and of its parts, are so faintly marked, and at the same time so entangled, that none but very general results can be reached."

The chief thing, then, that I would impress upon all beginners is the necessity for beginning work with a clear distinction between the aims and ends of Science and Art. When the art student has acquired enough knowledge—that is, Science—to express what he wishes, let him, with jealous care, keep the scientific mental attitude, if I may so express it, far away. On the other hand, if the student's aim is scientific, let him cultivate rigidly scientific methods, and not weaken himself by attempting a compromise with Art. We in the photographic world should be either scientists or artists; we should be aiming either to increase knowledge—that is, Science—or to produce works whose aim and end is to give aesthetic pleasure. I do not imply any comparison between Science and Art to the advantage of either one. They are both of the highest worth, and I admire all sincere, honest, and capable workers in either branch with impartiality. But I do not wish to see the aims and ends of the two confused, the workers weakened thereby, and, above all, the progress of both Science and Art hindered and delayed.

Next, I shall discuss briefly the ill-effects of a too sedulous study of Science upon an Art student.

The first and, perhaps, the greatest of these ill-effects is the positive mental attitude that Science fosters. A scientist is only concerned with stating a fact clearly and simply; he must tell the truth, and the whole truth. Now, a scientific study of photography, if pushed too far, leads, as a rule, to that state of mind which delights in a wealth of clearly-cut detail. The scientific photographer wishes to see the veins in a lily-leaf, and the scales on a butterfly's wing. He looks, in fact, so closely, so microscopically, at the butterfly's scales, that he never sees the poetry of the life of the butterfly itself, as with buoyant wings it disappears in marriage flight over the lush grass and pink cuckoo flowers of May.

I feel sure that this general delight in detail, brilliant sunshiny effects, glossy prints, &c., is chiefly due to the evolution of photography; these tastes have been developed with the art, from the silver plate of Daguerre to the double albumenised paper of to-day. But, as the art develops, we find the love for gloss and detail giving way before platinotype prints and photographic etchings.

The second great artistic evil engendered by Science is the careless manner in which things are expressed. The scientist seeks for truth, and is often indifferent to the manner of expression. To him, "Can you not wait upon the lunatic?" is, as the late Matthew Arnold said, as good as, "Canst thou not minister to a mind diseased?" To the literary artist, on the other hand, these sentences are as the poles asunder—the one in bald truth, the other literature. They both mean the same thing; yet what aesthetic pleasure we get from the one, and what a dull fact is, "Can you not wait upon the lunatic?" There are photographs and photographs—the one giving as much pleasure as the literary sentence, the other being as dull as the matter-of-fact question. The student with understanding will see the fundamental and vital distinction between Science and Art as shown even in these two short sentences.

And now, ladies and gentlemen, I do not think I can do better than finish this section by quoting another passage from the writings of the late Matthew Arnold.

"*Deficit una mihi symmetria prisca.*"—The antique symmetry was the one thing wanting to me," said Leonardo da Vinci, and he was an Italian. I will not presume to speak for the American, but I am sure that in the Englishman the want of this admirable symmetry of the Greeks is a thousand times more great and crying than in any Italian. The results of the want show themselves most glaringly, perhaps, in our architecture, but they show themselves also in our art. Fit details strictly combined in view of a large general result nobly conceived; that is just the beautiful *symmetria prisca* of the Greeks, and it is just where we English fail, where all our art fails. Striking ideas we have, and well-executed details we have, but that high symmetry which, with satisfying delightful effect, contains them, we seldom or never have. The glorious beauty of the Acropolis at Athens did not arise from single fine things stuck about on that hill, a statue here, a gateway there. No, it arose from all things being perfectly combined for a supreme total effect."

And now I must finish my remarks. I have not perhaps told you very much, but if I have succeeded in impressing upon beginners and some others the vital and fundamental distinction between Science and Art something will have been achieved. And if those students who find anything suggestive in my paper are by it led to look upon photography in future with a new mental attitude, something more important still will have been attained. For in my humble opinion, though it is apparently

* Concluded from page 252.

but a little thing I have to tell, still its effect may be vital and far-reaching for many an honest worker, and if I have helped a few such my labour will have been richly rewarded indeed. DR. P. H. EMERSON.

A QUARTER'S RESUMÉ OF PHOTOGRAPHIC PROGRESS.

[A Communication to the Birkenhead Photographic Society.]

THE Council of this Society have done me the honour of asking me to continue the quarterly summary of photographic intelligence so ably carried on by Mr. H. N. Atkins, who has left this part of the country and settled in Bristol. He was pre-eminently happy in this work. I accept the position under a deep sense of my unfitness, but am fortified in the belief that a willing hand meets with a ready response from those I desire to enlighten.

In making this quarterly statement, I propose to commence with hydroquinone, or, more properly speaking, quinol. The following are the best formulae I have tried. The first was given by Messrs. Mawson & Swan, Newcastle-upon-Tyne, with whose make of plates it answers admirably:—

A.	
Quinol	20 grains.
Citric acid	2½ "
Sulphite of soda	20 "
Water	5 ounces.

B.	
Caustic potass	40 grains.
Sulphite of soda	25 "
Water	5 ounces.

C.	
Bromide of potass	26 grains.
Water	1 ounce.

D.	
Caustic potass	40 grains.
Water	5 ounces.

Fix in a solution of hyposulphite of soda 1 lb.; water, 20 ounces. For usual exposures use equal parts A and B, adding 5 minims of C for every ounce of solution.

For over-exposed plates use D instead of B, with an extra quantity of C. For under-exposed plates omit C, and in extreme cases add 6 or 8 grains of sulphite of soda to every ounce of developer.

More or less sulphite gives more or less density.

This formula answers equally well for Ilford plates. Thomas's plates are better with their own developer, viz.:—

No. 1.	
Quinol	40 grains.
Sodium sulphite	½ ounce.
Citric acid	15 grains.
Potassium bromide	7½ "
Water	5 ounces.

No. 2.	
Sodium hydrate	40 grains.
Water	5 ounces.

Use equal parts of each solution.

Quinol acts differently, or rather indifferently, with certain plates, consequently plate makers must make their emulsion to suit quinol, and give over trying to write it down; they may just as well try to stem the torrents of Niagara with an umbrella. Photography, historically, is a history of one advance superseding another, and the sooner they discover this developer in that character the better for themselves.

The latitude it gives in exposure is its most valuable quality. It acts very well with Carbutt's flexible negative films, and is equally useful in developing bromide paper. I strongly recommend our members to adopt this mode of printing; it has a great future before it. Its other advantages are too well known to make it necessary for me to enter into further details; suffice it to say, professionals are readily taking to it, feeling the inevitable must be faced if they are to keep pace with the march of improvement.

The amateur, ever alive to the shortest way to the goal, must "make honey whilst the sun shines" in our short summers. I would also remind him that the prize slides of the winter now passing were slides reduced by the camera from whole and half-plate sizes to lantern size, 3¼ x 3¼.

Ha. tion is the next subject I have to bring under your notice. It is an old photographic trouble, well known in collodion days. I met with it in 1852, and overcame it with fine ground glass (on both sides, leaving no bright side for reflection); this proved an effectual cure, besides which, it quickened the sensitive plate. One-side ground is now becoming noised as a novelty. In very many cases we are only raking up the embers of the past. I sent a dozen of my double-sided ground glasses to Messrs. Mawson & Swan to sensitise for me, and have now the pleasure of placing them before you; one is taken with cross lights, which is the severest trial I can think of. I would call your attention to the prints

from the negatives, in which I think you will notice a certain softness peculiar to the treatment.

The stereoscope and how to stimulate its revival is my last subject. I make no effort to give you an exhaustive explanation of this delightful branch of our art-science. I must refer the novice to THE BRITISH JOURNAL ALMANAC for 1887, in which Mr. J. Traill Taylor, the editor, gives twelve chapters upon it.

I aim to reduce the appliances to the simplest form. To produce each picture to 4¼ x 3¼, so that two stereoscopically taken can be placed together, and seem like the old stereoscopic pictures 6½ x 3½, or kept separate as required. This plan gives an additional inch to its height, and this brings it into a standard size, 4¼ x 3¼. You can utilise them as single pictures, or make them lantern slides, or enlarge to whatever size you desire. I exhibit the arrangements I make in my dark slides to suit this arrangement. It may be made into a stereoscopic detective with the advantage of a larger picture. I exhibit prints for your inspection. I would also refer our students to an admirable article by Mr. B. J. Sayce in this year's BRITISH JOURNAL PHOTOGRAPHIC ALMANAC.

Our worthy president, Mr. Paul Lange, will not grant me more than ten minutes in delivery of my paper, so I must pause until next quarter-day.

JAS. ALEX. FORREST.

Foreign Notes and News.

At a recent meeting of the Society of Amateur Photographers of New York, Mr. Joseph Beach described a means of cutting out mounts for lantern slides so as to ensure them having a clean edge. A corset steel is sharpened on one of its edges, bent to the desired form, and fastened to a block of wood. It is placed upon sheets of paper, when, with one blow of a hammer, the mount is cut out.

THE following developing formulae have been communicated by Mr. D. Backrach, jun., to the Society of Amateur Photographers of New York, but do not essentially differ from many well known in this country. He says: "As I find the hydroquinone keeps better if meta-bisulphite of potash is added to it, my formula now reads:—

No. 1.

Hydroquinone	1 ounce.
Sulphite of soda	4 ounces.
Meta-bisulphite of soda	30 to 40 grains.
Distilled water	32 ounces.

No. 2.

Sal soda (crystals)	2 ounces.
Sulphite of soda (crystals)	2 "
Distilled water	32 "

I have also improved the formula, and secured much more clearness in the shadows and improved keeping qualities of the pyro solution, by additions to the former formula, and also avoid the staining of fingers. In rapidity of development for large numbers of negatives at a time, as well as for uniformity of result, this method, in my opinion, is without a rival. The following is the formula as improved:—

Solution No. 1.

Pyrogallie acid	1 ounce.
Sulphite of soda (crystals)	3 ounces.
Oxalic acid	30 grains.
Yellow prussic of potash	1½ ounces.
Meta-bisulphite of potash	120 grains.
Water	20 ounces.

First dissolve the sulphite of soda in the water (heated), then add the oxalic acid, the prussiate and the meta-bisulphite of potash, and finally the pyro, and filter.

Solution No. 2.

Stock solution of sal soda	1 ounce.
Stock solution of sulphite of soda	1 "
Water enough to make 8 ounces of developer.	

The stock solutions of the two sodas consist of one pound to half a gallon of water for each. The development by this process is so rapid that using partly old developer with it does not always restrain sufficiently, so in most cases an addition of a solution of bromide of potassium, before commencing to develop, to Solution No. 2 will be an advantage. For instantaneous exposures this is, of course, not required, and this method of development is especially advantageous for that sort of work. If no older developer is at hand to mix with No. 2, it will be necessary to add some bromide solution, also the first plates will come up too rapid and flat. Old developer (No. 2) is the best to mix with the new. I use one half as much of the old as I make of the new solution. This developer is also extremely economical (though I do not look or care for that), not over one-third the amount of pyro being used as in present used methods. In summer-time it may be necessary, when the solution cannot be kept cool, to add some astringent to the pyro solution to prevent softening of

the gelatine and frilling. In that case I have found bichloride of mercury the best thing to use, being without any effect on the action of the developer, only hardening the film and preventing decomposition. I have used ten grains to the twenty ounces of pyro solution given above, and a larger quantity will not hurt the solution."

Dr. BANNOW in the *Photographisches Wochenblatt* ascribes the rapid destruction of hydroquinone in its solutions to the employment of bad sulphite of soda, which readily oxidises to Glauber's salt (sulphate of soda). He recommends, consequently, the purchase of only good crystals of the salt, as the "weathered" specimens take up oxygen from the air much more readily. If this precaution be taken, alkaline hydroquinone solutions will remain good for months, and even solutions containing potash and soda for several weeks at least.

In our last issue we mentioned the interesting experiment of M. Bloch, in which he succeeded by employing a vessel, one side of which was composed of red glass, in rendering the development of a negative viable to a whole class. Last month's number of the *Bulletin de l'Association Belge de Photographie* gives the formula of the developer which he employed:—

To develop a negative 8 x 8—

Water	200 grammes.
Pyrogallie acid	2 "
Gallic acid	2 "
Acetic acid	4 "
Nitrate of silver	a few drops.

The bath was heated to about 25° (C.) to accelerate the development.

Dr. JESERICH, of Berlin, has recently been perfecting a method by means of which photography has still further been enabled to render assistance to the ends of justice. An action was recently brought against a man and wife of the name of Vogel, before the "*Landesgericht*" at Potsdam, who were suspected of having falsified certain documents. The defendants had in a previous civil action made use of a receipt as evidence. Dr. Jeserich's method succeeded in establishing the fact that the number 5 had in this receipt been converted into the number 56, the number 6 having been found to have been written with different ink and another kind of pen from the number 5. The two culprits were consequently sentenced to six months' imprisonment, during which period, it is hoped, reflection will have convinced them of the value of modern scientific improvements to society at large.

The firm of Ad. Braun et C^{ie}, in Dornach in Alsace, are preparing to add still further to the magnificent collection of reproductions of pictures which they have already published. They propose, namely, to issue carbon reproductions on 145 sheets of the Liechtenstein Gallery in Vienna. They have already published some thirty-six sheets, which are said to reproduce the features of the original in a very masterly fashion.

M. TURSCHLA-SIGNA communicates to the *Bulletin de l'Association Belge de Photographie* a method for giving a good brown colour to platinum proofs. He employs for this purpose a hot solution of neutral oxalate of potash, together with a solution of bichloride of mercury, employing as a developer,—

Solution A.	
Oxalate of potash	295 grammes.
Water	1 litre.

Solution B.	
Bichloride of mercury	5 grammes.
Water	100 cub. c.m.

Solution A is heated to from 70° to 80° C.; one then adds solution B. According as more or less of B is added, tones are obtained varying from a greyish blue to sepia brown.

The school for photographic instruction, established last year by Herr W. Cronenberg at Castle Gronenbach in Bavaria, already numbers some forty students, who have been attracted thither from nearly all the countries of Europe. Instruction is given in all branches of photography, and especially in printing.

CAPTAIN ENOCH HIMLY, who has acquired a high reputation through his experiments on hydroquinone, has been lately making some further trials on the action of that reagent in combination with ferrocyanide of potash. He has communicated some of his results to a recent number of the *Photographische Correspondenz*. He states that an addition of ferrocyanide of potash to the hydroquinone developer acts as a forcer, and is especially remarkable for the way in which it brings out the nuances of the negative. By employing a ten per cent. addition of ferrocyanide he found that an intense colouration of the film was produced, so that the time of development had to be shortened. Employing twenty per cent., and increasing the amount of sulphite of soda in the developer, the colouration

was found to be less intense, showing the action of the sulphite of soda to be antagonistic to that of the ferrocyanide. The fineness of nuance obtained in the case of the former experiment is said to be something astonishing.

The Amateur Photographic Club of Vienna held its thirteenth general meeting last month. Herr Carl Srna discussed the employment of pyrocatechin as a developer, and exhibited some negatives on which it had been employed. The Rev. Mr. Hechler gave a lecture on the light thrown on the early history of mankind by the excavations at Babylon, and in Assyria, Egypt, and Jerusalem. His remarks, which were very well received, were illustrated both by originals and by photographs of cuneiform inscriptions. Herr Seolik exhibited an interesting comparative collection of plates developed by hydroquinone and pyrogallol, as also some photographs of the solar corona, obtained during the recent eclipse of January 1 last. Among the exhibits the greatest interest was excited by the masterly reproductions of woodcuts and engravings which Herr Anton Emile had obtained by the wet process. Some of these which were printed on old paper were absolutely indistinguishable from the originals.

The Photographic Society of Switzerland will hold its next yearly meeting on May 6 next in the Hotel National, Zurich. A lecture will be given by Herr J. Brunner, of Winterthur, on the *technique* of Reproduction, which will be illustrated by exhibits.

Our Editorial Table.

THE LILLIPUT CAMERA.

By E. & H. T. ANTHONY & Co., New York.

ANOTHER of that small class of portable cameras, which are now becoming very generally demanded in America, is before us. Of very circumscribed dimensions, as shown by the peripatetic artist, at whose side it is slung, it yet contains one dozen plates, all ready for use. True, the plates are not large, being but two and a half inches square, but when the negatives this size are sharp their enlargement to two or three diameters presents no difficulty. Indeed, an 8 x 10 print from one of them which we have received along with several other originals, including the original of that special one, demonstrates the practicability of their bearing a considerable degree of amplification.

The camera is fitted into a neat case, which displays no external feature by which its nature could be guessed at by the public. On opening it the arrangements for holding the plates are found to be very neat. The six double dark slides are pressed forward

by a spring in the rear, and as each slide has a light and a dark top to its shutter the methods of exposing are systematised, so as to prevent confusion when operations have to be conducted under circumstances of pressure, as in a crowded thoroughfare.

Nine dozen sensitive plates are included in the Lilliput outfit, and as the pictures are taken on plates, the manufacturers claim as an advantage for their camera that no novelty in their manipulation has to be overcome by the user, and no danger encountered in any part of the world if not being restocked when the original supply of 108 comes to an end. The lens is rectilinear, and the shutter may work either instantaneously, or, if desired, with time exposures. It is a most elegant little camera, and reflects credit on its designers and makers.

We have before us a new style of developing dish. It is made of seamless steel, and enamelled with white porcelain. A special feature claimed for this dish is that if it were dropped on the floor, it would

not, like glass, porcelain, or vulcanite, be broken. In the bottom of the dish there are two ribs, and also three small cavities sunk in order to allow the easy removal of the plate. The corners of the dish are made at such an angle as to be thoroughly cleaned. It is manufactured by Messrs. Jones Bros. & Co., of Wolverhampton.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
April 22	North Middlesex Club	The Iron Room, Stroud Green.
" 23	Great Britain (Technical)	5A, Pall Mall East.
" 23	Bolton Club	The Studio, Chancery-lane, Bolton.
" 24	Burnley	Bank Chambers, Hargreaves-street.
" 24	Photographic Club	Anderton's Hotel, Fleet-street, E.C.
" 24	Burton-on-Trent	The Institute, Union-street.
" 25	Halifax Photographic Club	Mechanics' Hall.
" 25	Liverpool Amateur	St. George's-crescent North.
" 25	Oldham	The Lyceum, Union-st., Oldham.
" 25	London and Provincial	Masons Hall Tavern, Basinghall-st.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

APRIL 11.—Mr. A. Haddon in the chair.

The HON. SECRETARY read a letter from Mr. James Matthews, saying that at a future time he had no doubt he could exhibit to the Association some of the Douglass burners; Sir James Douglass had parted with his rights over the burners, and they are now under the control of a company in course of reconstruction.

The HON. SECRETARY next read a telegram from Mr. F. H. Varley, postponing the reading of a paper on *Testing the Speed of Shutters by means of a Siren*.

Mr. J. TRAILL TAYLOR wished to know if any one present knew anything about Mr. Blanchard's platinum process. He added that Mr. Lyonel Clark had worked out a platinum process; then he read the letter of Mr. Clark, which was published in these pages last week.

Mr. ANDREW PRINGLE believed that the first platinum paper introduced by Mr. Willis had silver in it.

The CHAIRMAN thought that such prints as produced by Mr. Clark might be fixed with cyanide of potassium, which would get rid of all the silver in the paper.

Mr. COX saw little advantage in process over the older ones.

Mr. J. J. BRIDGEMAN said that the advantage was in the printing right out; the operator could see what he was doing.

Mr. PRINGLE thought that Mr. Blanchard's process was simply toning by platinum salts.

Mr. TAYLOR said that Mr. Blanchard's process had not been made public, but was to be made known that evening at the Camera Club, no doubt at a later hour; so, if it were like Mr. Clark's, the first publication was at the London and Provincial Association.

Mr. PRINGLE remarked that at that moment it was half-past eight p.m. He thought it double trouble to make a silver print first and then to substitute platinum.

Mr. W. H. HARRISON doubted whether the prints by Mr. Lyonel Clark's process were permanent; he thought that they might consist largely of silver, and that toning was only a surface action. Once, to determine the latter point, he overtook a silver print on plain paper in the acetate gold bath for hours, till the picture was black and cold; then he soaked it for hours in dilute nitric acid, not strong enough to destroy the paper; in the half tones, as the residual silver dissolved, the colour grew warm and pink, resembling the colour of prints by several of the pure gold processes in which he had experimented; in the dark shadows the original blackness was unchanged with the time given in the nitric acid. He thought that prints by Mr. Willis's cold process should be tested for permanency as severely as those by the hot process had been tested.

Mr. TAYLOR remarked that in the burning-in process, in which a platinum image is substituted by toning for one of silver, no silver is left or the burnt image would look yellow.

Mr. COX had found his platinum prints to have a different colour when printed under unvarnished negatives which had been intensified by mercury.

Mr. P. EVERETT asked if any one had tried Dr. Hill Norris's new process.

Mr. PRINGLE said that two of the plates had been exposed on him; in one case the exposure was about the same as for a slow gelatino-bromide landscape plate; so far as he knew, no human being had ever seen the pictures developed on those two plates. The operator said that he sent all plates to Dr. Hill Norris to develop.

Mr. TAYLOR remarked that years ago an American prepared emulsion plates with an excess of soluble bromide, then dipped them in a silver bath as used in the old collodion days.

Mr. PRINGLE had, a few years ago, succeeded in making a collodion emulsion which gave fifteen on the sensitometer, but the emulsion would not keep twenty-four hours.

Mr. J. B. B. WELLINGTON said that collodio-bromide plates treated with erythrosine and ammonia had been made rapid enough to take camera pictures by Hastings's flash light; they had plenty of density.

Mr. A. MACKIE had made a rapid collodion emulsion, but it would give no density.

Mr. TAYLOR had known wonderfully quick plates to be produced by the aid of a preservative consisting of tannin and slightly alkaline gum. He believed the perfection of films, as regards thinness and fineness, to have been produced by Dr. Riley's hot water process, in which albumen was used as a preservative.

Mr. NESBIT said that collodion emulsion could be quickened, as stated by Captain Abney, by adding a few drops of solution of albumen in ammonia. The action is probably due to the ammonia. The films so produced are rotten, but they approach the sensitiveness of gelatine. There is a great difference in organifiers: he had found tannin to be safe and good; decoction of tea is good, but the plates do not keep. From what he had read of Dr. Hill Norris's new process, he thought that it would take up too much time to come into use.

Mr. WELLINGTON exhibited a portion of an unfinished detective camera, and explained the principle on which he had attempted to change plates therein.

Mr. F. P. CEMBRANO, in response to a question, thought the metal "preservers" of Mr. Hughes at the Crystal Palace Exhibition for binding lantern slides to be good, also Hughes's jet for the lantern, with three adjustments for centring the light. He had heard there that Ross & Co. were going to bring out a new lens in which the new Jena glass would be employed. The tourists' cameras of this firm were very compact.

The HON. SECRETARY stated that five or six years ago he was lecturing in Leeds, where Mr. Teasdale showed him some lantern slides he had bound with metal preservers. They might not keep out dust so well as paper binding.

The CHAIRMAN had carefully tried to repeat Mr. Friese Greene's experiment with the eye and a flash light, and had met with utter failure; he wished that Mr. Greene would give the Association some more information on the subject.

Mr. W. BEDFORD asked if the experiment could not be tried with an artificial eye.

Mr. TAYLOR said that the eye of a recently-killed ox might be tried.

The CHAIRMAN stated that the animal must be killed in absolute darkness for the purpose, or the visual purple of the retina would be first bleached.

CAMERA CLUB.

APRIL 11.—Sir George Prescott in the chair.

Mr. VALENTINE BLANCHARD gave an address and demonstration in reference to his platinum toning method. He referred to the serious difficulties attending ordinary platinum methods of printing, particularly for artistic work, where it was so necessary to see the printing throughout. He then described his method of toning the plain salted silver paper with his special toning solution, and went through the actual work, handing round the prints in the condition as taken from the frame, and at different stages in toning, and before and after fixing. The processes generally were the same as ordinarily used with gold toning. Mr. Blanchard recommending a warm toning bath and rather concentrated solutions. Additional interest was given to the demonstration by the exhibition of a large number of pictures printed and toned by the process, chiefly from collodion negatives. These showed in most cases a vigorous black colour.

On Thursday, April 25, Mr. Seyd will read a paper entitled *An Old Printing Process Revived*.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

APRIL 10.—An application for assistance was made, with the result that the amount asked for was granted. The correspondence having been dealt with, it was reported that the action taken re the contributions to the proposed Orphans' Fund had resulted in the following amounts being transferred to the General Fund:—*Photographic News*, 21*l.*; H. M. Smith, Huddersfield, 10*l.* 10*s.*; F. York, 5*l.*; F. Bedford, 2*l.*; W. Bedford, 2*l.*; R. & J. Beck, 1*l.* 1*s.*; and C. E. Elliott, 10*s.*

WEST LONDON PHOTOGRAPHIC SOCIETY.

APRIL 12.—The President in the chair.

Mr. CHARLES WHITING read a paper on *Lantern Slide Making*. The lecturer, in the course of his opening remarks, said he wished to impress upon his hearers the necessity of being exact with their formulae, clean in their manipulations, and, further, not to be disheartened by failures; there was more to be learnt from one failure than from a great many successes. Working by the wet collodion process, it was necessary to resort to reduction in the camera, and, in order to work with comfort, a suitable copying apparatus was necessary. He said he had made some rough experiments in toning by first converting the silver image into iodide of silver by means of a solution of iodine and iodide of potassium, afterwards treating it to a bath of sulphuret of ammonia; this changed the colour to a chocolate brown. He then proceeded to explain and demonstrate the production of lantern slides by the Woodbury process. In the matter of masks, it was advisable to suit the shape to the subject, more artistic results being then obtained. He then gave a practical demonstration of the production of a lantern slide by the wet collodion process, the development being effected by placing the exposed plate in a non-actinic glass tank in the optical lantern.

On April 26 a demonstration on *Enlarging* will be given by Dr. Harrison Low and Mr. John A. Hodges.

UNIVERSITY COLLEGE PHOTOGRAPHIC SOCIETY.

APRIL 9.—Dr. R. T. Plimpton in the chair.

Dr. H. FOSTER MORLEY read a paper on *Hydroquinone and its Uses as a Developer*.

After some reference to the discussion which has been carried on in the pages of THE BRITISH JOURNAL OF PHOTOGRAPHY relative to hydroquinone and the supposed great differences between samples from different sources, Dr. Morley proceeded to point out that while benzene C_6H_6 is a very stable substance, the more oxygen introduced into its molecule, the more prone is the product to oxidation. Mono-oxy-benzene C_6H_5O , known as phenol or carbolic acid, has but little reducing power; the three di-oxy-benzenes—resorcin, hydroquinone, and pyrocatechin, all of which have the formula, $C_6H_4O_2$ —have considerable reducing power, whilst tri-oxy-benzene $C_6H_3O_3$, or pyrogallol, possesses this quality in a remarkable degree. The reactions of these bodies with ammoniacal solution of silver nitrate and ferric chloride were then described and illustrated by actual experiment with the former.

Resorcin gives no precipitate; but on boiling, reduction takes place, and a black precipitate of metallic silver is thrown down. Hydroquinone gives a greyish-white precipitate, changing on boiling to black metallic silver; whilst pyrocatechin and pyrogallol acid instantly precipitate metallic silver from ammoniacal solution, even in the cold. The reactions with ferric chloride are even more characteristic, hydroquinone gives beautiful dark needles of green hydrate and an odour of quinine, resorcin gives a purple colour, pyrocatechin a green colour, and pyrogallol a violet colour, instantly changing to reddish-brown. Pure hydroquinone may be recognised by its melting-point, which is stated to be 169°C ., but which in a very beautifully crystallised sample was found to be 167°C . A sample which had been kept in the dry state for about six years was found to melt at 168°C ., showing that it was practically unchanged. Hydroquinone may be burned on a platinum spatula without leaving any residue, not even carbon. This test will at once reveal the presence of sodium sulphite and other possible impurities. The purity of hydroquinone may also be tested by a decinormal solution of potassium permanganate. If six milligrammes of hydroquinone be dissolved in fifty cubic centimetres of water (distilled), four c.c. of strong sulphuric acid be then added, and the liquid heated to boiling, 11.3 c.c. of permanganate must be added before the pink colour becomes permanent. This quantity corresponds to a consumption of eight atoms of oxygen by each molecule of the permanganate. As regards development by hydroquinone, Dr. Morley maintained that, unless an alum bath be used, there is great risk of local staining during the progress of drying. He recommended its use both before and after fixing. The developing solution might be heated to 30°C . with advantage, but a higher temperature is attended with considerable risk of blistering. Twenty-four grains of hydroquinone were found to be sufficient to develop four whole plates in succession; plates so developed were shown and were pronounced very satisfactory.

In the discussion which followed, Mr. J. T. LEON said that he had made similar experiments with permanganate to those described by Dr. Morley, and had arrived at substantially the same results. As to the use of the alum bath, he was of opinion that it was sufficient to use it after fixing.

Mr. NORTH had observed this tendency to ink stains on negatives developed with hydroquinone, but had always attributed them to an insufficient quantity of developer; very similar stains were produced in ferrous oxalate development.

Mr. GUNN had observed, in making enlargements, that one corner of the paper was almost invariably stained, and after much investigation had discovered that it always occurred at the corner of the dish from which the developer was poured off, and was presumably due to the action of old developer which had crystallised at that corner, for, on carefully washing the dish after each operation, the stains no longer appeared; possibly the staining by hydroquinone might have some similar explanation.

Dr. MORLEY having replied, the meeting adjourned till Tuesday, May 14, when the Secretary will read a paper *On the Application of Photography to Book Illustration*.

EAST DULWICH AND PECKHAM PHOTOGRAPHIC SOCIETY.

APRIL 12.—Mr. L. Warnerke in the chair.

The CHAIRMAN addressed the meeting as to the necessity of making the Society a really strong one, and on the manner to accomplish this end, giving them some good, sound, practical advice.

A portrait taken by the flash light, the work of Mr. Herlert, one of the members, was handed round, and met with general approval, it having been taken by a lamp of his own construction.

Mr. WARNERKE kindly consented to take the chair at the next meeting, which will be held at Mr. Seaton's Music Warehouse, 76, Peckham-rye, on Friday, May 3, when he has promised to explain flash light photography, and also to give other interesting communications to the Society.

Gentlemen, both amateur and professional, are invited to attend.

BRIGHTON PHOTOGRAPHIC SOCIETY.

APRIL 9.—The President (Dr. Bean) in the chair.

Mr. D. E. CAUSH read a paper on *Bromide Printing*, which dealt with the subject in an exhaustive manner, and was illustrated by several prints developed by the ordinary ferrous oxalate developer and also with hydroquinone. Mr. CAUSH also passed round several fine enlargements of microscopic subjects.

At the conclusion of the paper an animated discussion ensued.

IPSWICH PHOTOGRAPHIC SOCIETY.

APRIL 9.—The occasion being a lantern night there was a large attendance. Nearly two hundred slides, sent in by Messrs. Cash, Booth, Edwards, Fry, Orchard, Pringle, Read, Vick, Wiggan, Woolcock, and Younger were projected, and showed a decided improvement over those exhibited at the first exhibition in December last.

The first outdoor excursion of the season is fixed for Saturday, May 11, and will be to Holbrook.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

APRIL 11.—Mr. W. Jerome Harrison, F.G.S., in the chair. There was a large attendance.

The meeting was made special for the purpose of a lantern display by the Lantern Committee of the slides lent by the Birkenhead, Liverpool, and Ulster Societies. They were shown on a twelve-foot screen by powerful lanterns, and, with few exceptions, proved very fine slides. They were much appreciated and gained much applause.

The CHAIRMAN announced the subject (*Cameras and Appliances*) for the next meeting.

BRADFORD PHOTOGRAPHIC SOCIETY.

APRIL 9.—The date for sending in pictures to the forthcoming exhibition was fixed for June 3, the exhibition to be opened on June 6, at the Art Museum, Darley-street. Prizes will be given, consisting of silver and bronze medals, in each of the eleven classes.

After the ordinary business was concluded, the members adjourned to the laboratory, where a lantern slide exhibition was held, at which one hundred and fifty slides, made by the members, were shown.

Two specimens of psychic photography were shown by one of the members, discussion on which was adjourned until the next meeting.

Secretaries of other societies will please note that the Hon. Secretary's address is Mr. Walter Leach, 50, Godwin-street, Bradford.

BIRKENHEAD PHOTOGRAPHIC ASSOCIATION.

APRIL 11.—The President (Mr. Paul Lange) in the chair.

Messrs. H. Cockburn, W. H. R. Kerry, F. Hope-Jones, and C. J. Turton were elected as members.

Mr. J. A. FORREST read *A Quarter's Resumé of Photographic Progress* [see page 270]. Mr. Forrest also exhibited some stereoscopic pictures and apparatus.

Mr. H. Wilkinson exhibited a single dark slide which found favour amongst the members, its weight not exceeding two ounces.

The PRESIDENT then announced that Mr. Walter Wilkinson would read a paper on *The Art of Retouching*. [This will appear subsequently.]

Mr. WILKINSON then passed a 10×8 negative round with two portraits on, both being of the same person and exposed alike; he stated that one he had retouched so that the members might see both side by side, and also see the advantage of retouching in portraiture. In reply to a question, Mr. Wilkinson stated that he used turpentine and resin as a medium for his negatives.

On the proposition of Mr. Paul Lange, seconded by Mr. J. H. Day, a hearty vote of thanks was tendered to Mr. Wilkinson for his excellent paper.

Mr. JOHN HARGREAVES, F.R.H.S., then gave a very descriptive account of the slides *Illustrated Boston*, which were shown on the screen, the slides having been made by the members of the Boston Camera Club.

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES' PHOTOGRAPHIC ASSOCIATION.

APRIL 9.—Mr. H. R. Procter in the chair.

Mr. G. Proud was elected a member.

Mr. M. Auty exhibited a home-made hand camera to take half plates, which was much admired.

Mr. J. P. GINSON read a paper on *The Intensification and Reduction of Negatives*.

A discussion followed.

The outdoor meetings for the season were arranged as follows:—Richmond (Yorkshire), Wooler and district, Warkworth, Staward-le-Peel, and Castle Eden.

HASTINGS AND ST. LEONARDS PHOTOGRAPHIC SOCIETY.

APRIL 9.—Mr. W. Thomas gave a clever exhibition of photo-micrographic slides, accompanied by some valuable descriptive observations. Afterwards there was a lantern slide competition, Mr. A. Brooker having offered a prize, consisting of a gross of lantern plates, for the best four slides, to be the sole work of the exhibitors. The award was secured by Mr. Thomas, jun. (the audience being the judges), and as Mr. Pierson, another member, ran Mr. Thomas

so closely, in the opinion of those present, Mr. Brooker announced that he should present another prize to the gentleman mentioned. Some miscellaneous pictures were then shown on the screen, among them being subjects by the Rev. — Macdonald (Norwegian views) and the Rev. A. B. Cotton, who has recently returned from a trip abroad, and has brought with him further evidences of his photographic and artistic skill.

It was announced that at the next meeting, May 7, Mr. H. F. Bultz will read a paper on *Instantaneous Photography*.

SOUTHPORT PHOTOGRAPHIC SOCIETY.

On Monday evening the President, Mr. Benjamin Boothroyd, and Mrs. Boothroyd, gave a *soirée* to the members and their friends in the Hall of the Y.M.C.A. The gathering was a most successful and enjoyable one, there being about eighty guests present. A capital programme, consisting of "picture, song, and story," was gone through, Mr. Nichols, of the Liverpool Photographic Society, being loudly encored for his original "Photographic Song."

A short address was given by Mr. BOOTHROYD, in which he congratulated the members upon the success of the Society up to the present, and hoped that the year upon which they had just entered would be even more successful.

The latter part of the programme consisted of a lecture by Mr. EARL, of the Liverpool Photographic Society, entitled, *Shots with a Detective in Belgium and Holland*, illustrated with limelight views.

DERBY PHOTOGRAPHIC SOCIETY.

APRIL 9.—Mr. R. Keene presiding.

Mr. E. J. LOVEJOY (Hon. Secretary) gave a demonstration on *Developing and Intensifying Gelatino-Bromide Plates*.

The first outdoor excursion of this season is arranged for April 27 to Ashby-de-la-Zouch, when the members of the Nottinghamshire Association will meet the members of this Society.

LEICESTER AND LEICESTERSHIRE PHOTOGRAPHIC SOCIETY.

APRIL 11.—Mr. George Bankart in the chair.

Three members were elected.

Mr. PICKFORD gave notice of his intention at next meeting to offer a silver and bronze medal for enlargements, to be competed for by the members.

Mr. THOMAS SCOTTON, of Derby, gave a demonstration on bromide printing and transfer to opal. Mr. Scotton thoroughly established the transferotype

in the estimation of the members present. Mr. Scotton afterwards exhibited several magnificent enlargements.

At this meeting the bronze and silver medals were presented by the President to the successful competitors at the late exhibition of prints and lantern slides, namely, Messrs. George Bankart, W. T. Tucker (2), J. Porritt, A. W. Wilson, and W. Taylor.

PHOTOGRAPHIC SECTION OF THE PERTHSHIRE SOCIETY OF NATURAL SCIENCE.

THE first meeting of this Section was held on the 8th instant,—Dr. F. B. White, F.L.S., in the chair. There was a good attendance.

The CHAIRMAN explained the connexion of the branch with the parent Society and the scope of its work. He expressed the hope that much would be done in elucidating the geology and topography of Perthshire by the members of the Section.

He then introduced Mr. FREW, F.C.S., who read a paper on *The Printing Processes*, which he illustrated by numerous specimen prints. He referred in turn to the ordinary silver print, the newer bromide paper, the autotype, the platinotype, and cyanotype processes, and pointed out the characteristics of each.

A reference by Mr. Frew to the work done by Mr. Blair, a Perth man, in perfecting the autotype process, led to an animated discussion on the claims of that gentleman as an inventor.

A limelight exhibition followed, the slides exhibited being the work of Dr. Urquhart, Messrs. R. D. Pullar, Frew, Munro, and Ellison (the Hon. Secretary). For the purpose of illustrating Mr. Frew's paper, a collection of prints by the various processes was kindly lent by the Autotype Company, the Platinotype Company, the Eastman Company, and Messrs. S. Fry & Co.; and also engineering plans and drawings by Mr. Reid, of University College, Dundee.

Correspondence.

Correspondents should never write on both sides of the paper.

APRIL MEETING OF THE SOCIETY.—DONATION OF VALUABLE PAPERS.—THE GAILLARD PRIZE AT LAST AWARDED, OR PARTIALLY SO.—DONATION OF PHOTOGRAPHIC MANUALS BY MM. GAUTHIER-VILLARS & SONS.—A NEW PANORAMIC CAMERA.—M. DARLOT PRESENTS A PORTABLE CAMERA.—A RESULT OF EXPERIMENTS BY M. TONDEUR.—M. LANSIAUX PRESENTS A CAMERA.—PROOFS "IN NATURAL COLOURS."—A NEW VARNISH.—A RAPID SHUTTER.—COMIC SCENES, ETC.

THE Photographic Society of France held their monthly meeting on Friday evening last, the 5th instant, M. Davanne in the chair.

M. Rolland, grandson of M. Carpentier, personal friend of the celebrated Daguerre, made a donation to the Society of different writings relating to the inventor of photography and to his personal acquaintances.

M. Audra read the report of the commission which was named to award the Gaillard Prize. It may be remembered that this gentleman offered 500 francs to any one who could invent an original process for printing positives rapidly. One person only came to the front, and presented the well-known gelatino-bromide process by development. The commission in their report agreed that the process, though giving very good results, did not merit the prize, but agreed that it would be well to award M. Thiebaut 300 francs as an encouragement.

MM. Gauthier-Villars & Sons made a donation to the Society of several works on photography. I shall have the occasion on my return to Paris to give an account of them.

MM. Benoist & Sons presented a new panoramic camera. It turns upon its axis, during which movement the sensitive plate passes behind the lens, and the impression is thus regularly received. The size of the plate is 18 x 50 centimetres. The prints submitted to the inspection of the members were very large, but presented distorted lines and other faults, which perhaps may be eliminated by practice. Two other apparatus were exhibited by the same gentlemen, one being a stereoscopic camera.

M. Darlot, the well-known optician, presented a half-plate camera, its great value being its taking up very little room and very light for tourists.

M. Tondeur informed the Society of the result of some of his experiments in endeavouring to develop during exposure. "I saturated a plate," said he, "with hydroquinone, placed it in a dark slide, and exposed it in the camera. If sufficient exposure be given the negative can be completely developed during the exposure, if insufficiently exposed the plate must be allowed to remain until all the details have been brought out."

M. Tondeur presented a kind of "minocle" or eye-glass, but instead of being of a transparent substance it is made of ebonite. In the centre is a very small hole. He says that by placing this kind of disc before the eye one can judge of the colour of the rays of light, and their actinism can be, as it were, seen, and thus the time of exposure more accurately determined. "One morning," said he, "I was in the street with one of my colleagues, and wished to take an instantaneous view. The light appeared to us very good and suitable. I put the little instrument to my eye, and the light now appeared of a yellowish tint; the faces of the passers-by took a reddish colour. I had not yet sufficient faith in the instrument, and I determined to take a shot. The result was deplorable.

On another occasion the light appeared to me too dull; I put the apparatus to my eye, and was surprised to see that the surrounding objects appeared of a bluish-white tint. The plate was exposed, and a magnificent, fully exposed negative was the result. I must say that I should never have dared to expose a plate in such a light had it not been for the instrument which I now present to the Society."

M. Tondeur intended to exhibit a new rapid shutter, but was desired to postpone it until the next meeting.

M. Lansiaux presented a small hand camera, which he has designated "Photo Express." This camera has attached to it a changing box, so arranged that the twelve plates it contains can all pass behind the lens in less than two minutes. This will indeed be very useful for those who make instantaneous views.

M. Vallot presented a number of proofs "in natural colours" obtained by light, by, said he, the process of Poitevin. All that I can glean is, that after having obtained a coloured image by a prolonged contact under a coloured substance, M. Vallot has succeeded in making the colours obtained a little more durable by an immersion in a bath of sulphate of quinine and a little of the tincture of saffron.

M. Schaeffner presented a new varnish, which offers, says he, many advantages over the old:—1st, It is perfectly transparent; 2nd, The negative need not be dried nor heated; 3rd, No loss of liquid, as the solution can be used over and over again; 4th, It takes the pencil and all kinds of retouch; 5th, It is not superficial, but enters the pores of the negative. This varnish he calls "Hydrophile." It has the advantage of never cracking when dry.

M. Carguero presented a rapid shutter with which a great variety of exposure can be given. Its best feature is that it is small, and takes the place of the diaphragma.

MM. Balagny and Coppeaux presented a great number of proofs representing laughable scenes. These comic pictures obtained great success. One picture represented a farmyard, the milkmaid about to draw water from the well. She appears not to be able to do so, the bucket of water being too heavy, and is seen calling for aid. In the second, a soldier assists her, and is seen pulling at the cord. The bucket will not rise. In the fourth, another servant assists them, and the three are pulling with all their might and main. In the fifth, the whole three are on the ground, the cord having broken. Many such subjects were exhibited and created merriment.

The meeting separated rather late.

PROF. E. STEBBING.

Rome, Italy.

PREVENTION OF YELLOW STAINS.

To the Editor.

SIR,—In the JOURNAL of 23rd September, 1887, I published a formula with the addition of sal ammoniac to the carbonatis. I have also used it with ammonia to advantage. I have lately tried caustic potash, which is generally regarded unfavourable to pyro development, and find with the plates I use (Ilford) to give negatives equal to ammonia without the objectionable fumes, &c., and equally quick in development.

FORMULA.

Caustic potash (sticks)	4 grains.
Sal ammoniac (ground)	4 "
Bromide ammonia	½ grain.
Water	1 ounce.
Pyro (dry)	2 grains.

—I am, yours, &c.,

Southport, April 13, 1889.

J. C.

GELATINE PLATES FOR LANTERNS.—A QUERY.

To the Editor.

SIR,—A question has arisen as to the date of the commercial introduction of LANTERN plates. By lantern plates is meant thinly coated gelatine plates, 3½ x 8½. My recollection of the matter is that they were first introduced commercially in the winter of 1884—this opinion is supported by advertisements and other evidence. On the other hand, one maker claims to have introduced them in 1880, while another party says that they were in the market seven years ago. As the question of who first had the credit of introducing lantern plates commercially might as well be settled, I would feel obliged by the expression of the opinion of some of the readers of your valuable JOURNAL on this question.—I am, yours, &c.,

J. M. TURNBULL.

6, Rose-street, Edinburgh, April 15, 1889.

PHOTOGRAPHING IN FRANCE.

To the Editor.

SIR,—I have observed that there occasionally appears, from some of your correspondents, a species of onslaught against France and on us French; I mean, of course, as regards photography. It is only the other week when it is averred that one man was obliged to leave Brittany alone, and another advised the photographer to leave France and Germany alone. Why? Because he had some imaginary trouble with the Custom House. I say all this is mere bosh, and nobody would lose anything by leaving it untold. Of course you are right when you say that all should be said for and against, and let the public be judge and

make up his mind; but then why, yes why, do you allow always remarks against France to pass, and nothing in favour of it?

Now, please be fair, and state, after reading carefully *THE BRITISH JOURNAL OF PHOTOGRAPHY*, what country would you go to, and what would you avoid? My experience, after reading such, would be to stay at home. Is this your idea of what would be really advisable? Your correspondents in later issues say, avoid France, Germany, and Norway, and so on about every country in Europe, except England. Will you please also note my own experience in free and defectless England. When I came over once I had two dozen plates with me unexposed. I had all kinds of trouble and fuss with Custom-house officers at Charing Cross, London, to be allowed to pass without opening them. Had I not been conversant with the English language, I have no doubt they would have been opened. Next, two years ago I made an extensive tour in Europe, and from Brussels I sent to Messrs. Wratten & Wainwright (they can swear to it) a box of six dozen exposed plates. I marked them as sensitive to light, and inside of box wrote an extensive label explaining the contents, and asking not to have them opened (the plates) except before Wratten & Wainwright. Nothing did help, and one dozen was opened, and, of course, spoiled. Now, my say is, and I have as much right to it as your other correspondents, I say, emphatically, *avoid England*. What next? Where is a man to go if he reads *THE BRITISH JOURNAL OF PHOTOGRAPHY*? Avoid everything is said therein; protests have no show.

Here is what I would say. Avoid no country, but make up with every country's customs, specially so if you are ignorant of its language, and do not think that because you are *English* you necessarily must pass free everywhere, and have less trouble than the inhabitant of such country himself has. I have travelled a great deal you know, and my experience is as follows:—England: my experience was as above; in case of need I would go there again anyhow. Belgium: I found very easy to get plates through Custom by explaining matters. Holland: the plates are opened at frontier of country, and if you are not there you are bad off. Take your plates along with you, but do not avoid Holland for that. France, Germany, Austria, Switzerland, and Italy are all very easy to pass at the Custom House or at the frontier, provided you explain politely to the official how matters stand. I have no difficulty whatever in those countries. I must, however, add that I spoke the different languages of these countries, and this made of course matters easier. I would say here that in most cases, if not all, you can find in the different cities you go to in Europe (Continent) *some one* speaking English or French; and let me tell you this is more than you can say about England, where you cannot find at a station and most of the hotels, small or big, probably one party speaking French or German out of one hundred. English is spoken at Calais, but I never heard any one speaking French at Dover or London, for that matter, at the stations. However the case may be before starting, an Englishman expecting some trouble with his plates can have a friend (learned) write for him—in the different languages of countries he intends to visit—on a card the different objections to opening the packages, and this would probably settle most, if not all, difficulties. Now, I intend to bring this matter, if possible, before the French Societies here, and have this systematical *avoid France* ventilated somewhat; and when Englishmen do come over, this matter can be talked about specially, that foreigners will be cordially welcome here during the exhibition, and maybe these very *avoid France* will be foremost in accepting the invitations. Hoping again for fair play—I am, yours, &c.,
A. LEVY (Paris).

TRANSPARENCIES WITH ORNAMENTAL BORDERS.

To the Editor.

Sir,—I am much obliged to Mr. John Robertson for his kind wishes, and am interested in hearing of his experiments of eighteen or nineteen years ago. But let me hasten to assure him that there is nothing in my patent to prevent him producing "such pictures," so long as he continues to confine himself to *collodion*. If Mr. Robertson will kindly read the specification again, he will find that the claim is made for the use of *gelatine emulsions* only.

I of course knew nothing of Mr. Robertson's experiments, and had some idea of making a wider claim; but remembering the indefatigable industry of innumerable workers during the long reign of *collodion*, I thought it only too probable that from some "repository of exploded ideas" might come some ancient relic to drop upon me "like a ton of bricks." As, moreover, plates coated with *gelatine emulsion* were the only ones likely to be of me of commercial value, I restricted myself to the use of that material. Whether silver images in *gelatine* are or are not permanent when exposed to sunshine is a question I will not attempt to argue. It has already been pretty freely discussed in your columns.—I am, yours, &c.,
WM. J. WILSON.

Editing, London, W., April 13, 1889.

"SWEATING."

To the Editor.

Sir,—In your issue of April 12, I notice the letter of "Fair Play," calling attention to the above subject; but he will perhaps not be surprised when I tell him that in our district (Huddersfield) we have not

only a great many who supply *cartes-de-visite* at half-a-crown per dozen, but we have one in particular who is crowding the country with them at 1s. 3d. per dozen, and this has been going on for some years past.

"Fair Play" says they will hurt the profession in the future; but they hurt it now, and very much so. He also asks, "Can some one suggest a remedy?" I can suggest one which I think would help it a great deal, but perhaps it would not altogether stop it—that is, the abolition of Sunday work. A few miles from here, not long ago, a photographer was summoned and fined for opening his studio and taking photographs on a Sunday, so there must be a law against it, or they could not have fined this man. A fortnight ago I was on a visit to a friend at Hull, and there, the Sunday through, in one of the main streets, two or three men stood touting to every passer-by, people going to the different places of worship, and the most surprising thing to me is that these people do not inquire into it. If they did I think they could have it stopped. I enclose you a price list certifying to the accuracy of these charges, or your readers might think I was stretching it a little. Hoping to hear something further said upon the matter—I remain, yours, &c.,
DHARWAR.

April 15, 1889.

[Price list referred to has been received.—Ed.]

FLASH LAMPS.

To the Editor.

Sir,—I observe a notice in your *JOURNAL* of the 12th instant, page 260, wherein are these words: "Connecting pieces are also supplied by which two or more lamps may be ignited simultaneously." Such a direction-post may lead your readers to a bog, wherein they are likely to soil their reputation and upset their finances. To enable them to avoid such, allow me to quote from Patent, No. 356, 1888. The sixth claim is as follows: "In flashing lamps the combination of the multiple distributor, with air or gas under pressure, for producing two or more simultaneous flashes of light." The method recommended (in the same notice on page 260) for igniting the magnesium—also a species of plagiarism—I can leave to whosoever it may concern; but I should be surprised to learn that any one would reclaim or dispute with Mr. W. England the authorship of such an ambitious application for oxydising a metal as that of mixing it up with *heated hydrogenous vapour* or gas.—I am, yours, &c., F. W. HART.

P.S.—In looking through the same number of the *JOURNAL*, I notice Schirm's specification has a like misleading paragraph relating to distribution.

CRYSTAL PALACE EXHIBITION.—A CORRECTION.

To the Editor.

Sir,—In the list of awards published in the *JOURNAL* of April 5, amongst the Special Medals, I find my name given as "G. Gillard, Glasgow." It should be W. Gillard, Gloucester.—I am, yours, &c.,
W. GILLARD.

The Studio, Clarence-street, Gloucester, April 15.

Exchange Column.

* No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

Whole-plate rolling press, hot, offered in exchange for studio accessories.—Address, W. T. SMITH, 29a, Bold-street, Liverpool.

World type writer, value two guineas, for whole-plate dry plates.—Address, PHOTO, 4, Latham View, Wright-street, Egremont, Cheshire.

Will exchange Victoria camera with four lenses for first-class cornet, Besson's preferred.—Address, W. S. POOLSON, 30, Great Jackson-street, West Gorton, Manchester.

Wanted, apparatus and studio furniture, &c., whole-plate tourist camera, not less than three double dark slides, portrait lenses (Lerebours' or other maker's), posing chairs, &c.—Address, PHILLIPS, Oxford House, East Croydon.

Will exchange quarter-plate portrait lens and quarter-plate bellows-body studio camera by Lerebours & Secretan for half-plate portrait lens by same makers.—Address, W. CHADWICK, 82, Spring Bank, Higher Blackley, near Manchester.

Eight-inch burner with three feet india-rubber tubing, light background (cloth) on roller, portable head rest (nickel-plated) for use on ordinary chairs, all in good condition; will exchange for good wide-angle lens, half-plate.—Address, W. G. O., 33, George-street, Chesham-hill, Manchester.

JOURNAL ALMANACS, 1885-1888; News Almanacs, 1884-1888; American Annual, 1888; forty-one BRITISH JOURNALS, 1885-1889 (various); one hundred and eighteen *Photographic News*, 1884-1888 (various); fifteen *Photographer's Worlds*. Exchange for Ilford dry plates to value.—Address, S. WILLIAMS, Portrait Rooms, 181, Brighton-terrace, Hartorne.

Owing to our publishing one day earlier, several announcements and reports received too late must stand over till next week.

INTERNATIONAL AND INDUSTRIAL EXHIBITION, YORK.—We remind our friends who intend to exhibit photographs and apparatus that all applications must be sent in by the 5th, and all pictures delivered carriage paid before the 25th of May. Neither Oxford nor oval frames will be admitted. Application must be made to Mr. Joseph Davis, General Manager.

Answers to Correspondents.

•• Communications relating to Advertisements and general business affairs must be addressed to "H. GREENWOOD & Co., 2, York-street, Covent Garden, London, W.C.

All matters for the text portion of this JOURNAL, including queries for "Answers" and "Exchanges," must be addressed to "THE EDITOR," 2, York-street, Covent Garden, London, W.C. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.

PHOTOGRAPH REGISTERED:—

J. Somme, jun., Oxford.—Photograph of a boy dressed in academical cap and gown, with two bulldogs, entitled "The Proctor."

STARK.—The payment of fare is purely a matter of arrangement.

R. L.—It is quite true that flash-light photography was tried in 1865.

M. M.—The negative has evidently been fogged by light entering at the end of the dark slide.

SHIKABE.—If your solicitor will write a letter to the firm it will probably have the desired effect.

FRITZ.—A six and a half inch condenser will be quite large enough for enlarging from a five by four negative.

RAPID.—If your flap shutter attracts the attention of children in the studio it can be fitted inside of the camera.

A. G.—We are unable to institute comparisons between the three lenses mentioned, as we only possess the one already described.

IMITATIVE.—To obtain a gloss on an unmounted print, pass it through a burnisher in conjunction with a sheet of cardboard.

T. writes: "I find that when a blue print comes in contact with ammonia it turns violet. Has this ever been published?"—Yes.

G. SINCLAIR.—Strengthen your alcohol by shaking it up with dry carbonate of potash and decanting the upper portion of the liquid.

SULLONE.—The Zentmayer photographic objective was introduced in 1886. It is a doublet of two simple crown-glass lenses, but of an unusually deep meniscus form.

B. (Tottenham).—Neutral chloride of copper can be made by dissolving the black oxide of copper in hydrochloric acid and the solution evaporated and crystallised.

PARSON & RAF write: "Can an 18×16 negative of a landscape be taken with a single lens? and, if so, what focus should it be?"—Yes; about twenty-six inches focus.

JAMES S.—1. The bottle came to hand; the name on it is done by means of the sand blast.—2. No, it is done after the bottle is made; any piece of glass can be lettered in the same way.

LEONARD WILKINS.—The negative has been returned. You can easily intensify the particular portion spoken of by mixing Judson's yellow dyes with gum senegal and applying it by means of a small brush.

WM. BETTS, JUN., asks what is the correct way of mounting stereoscopic pictures, the edges of the prints touching or by leaving a small space between them?—Trim the prints so that when mounted a small space intervenes.

W. C. J. sends some plates with wave-like markings on them, and inquires the cause.—The markings are due to uneven drying. If, when the plate begins to dry the drying be arrested, marks such as those shown are sure to be produced.

R. B. BULL wishes to know "which is really the best artificial light for portraiture, the electric or the magnesium flash light?"—Good portraits can be produced by the flash light, but for general studio purposes the arc light is infinitely superior.

ONE IN DOUBT.—If you have made use of any words imputing fraud to the tradesman in the transaction of his business an action will lie, even although no proof of special damage be forthcoming. To save trouble, you should at once tender an apology.

B. M. asks: "Where can I obtain a compound frame for negatives of various sizes, as shown on page 126 of Hepworth's *Book of the Lantern*? I cannot find one in any catalogue."—Such frames are not usually kept in stock, but have to be made to order.

J. E. WOOD asks which are the best pencils to use in retouching negatives, and by which maker.—The pencils most in use by retouchers are H, HH, up to six Hs. Sometimes a softer pencil, such as B or HB, is used, but very rarely. Many people prefer Hardtmuth's leads.

POTASH sends specimens, and would like to know if he has any chance of being taken as assistant at a moderate salary, 15s. or 17. per week. He does not know very much about portraiture.—The specimens are excellent, and doubtless many would be glad of his services at the price mentioned.

M. D.—There is nothing extraordinary in the print you send. The fact that it has bleached on that portion which has been exposed to the light, while that part which has been protected by the ink has retained its pink tint, is well known. The pink tint of all albumenised papers will be discharged by exposure to light.

NOVICE.—Proper lithographic transfer ink may be obtained from Winstone & Sons, Shoe-lane. It will be far better for you to purchase the small quantity that you will require than to attempt to make it yourself. Moreover, you will be sure that you have the right thing, so that you cannot attribute your failures, if you meet with any, to the ink being at fault.

X. Y. Z.—1. By selling the lens without any name no risk whatever is incurred; but if you engrave your own name on it without stating that it was made abroad you are liable to be proceeded against.—2. During the probationary period of a patent no manufacture can legally be marked as "Patented," but it is lawful to mark it as "Patent applied for."

R. WILMORA writes as follows: "I have a quantity of gold bead frames which have turned quite black in places. Can you tell me how to regild them, or is this an operation that is too difficult for a novice to undertake?"—The frames in question are doubtless common German bead, which is simply the moulding covered with silver foil and then lacquered. New bead is so cheap that it will not pay to do anything in the way of restoration to the old.

OPTICIAN.—1. We are not yet in a position to give plain working directions for staining brass black by the copper process, but enough has been already published by us to enable any one to work out details in practice for himself.—2. It is quite true that a solution can be prepared by which a black colour can be imparted without heat, a fact we have many times proved, although we have not yet got the process formulated quite so nicely as we desire.

A. J. C. says he has been sensitising some paper according to a formula a friend gave him of ten grains of citric acid to each ounce of a forty-grain bath. The paper, he says, keeps white for a long time, but it will not tone beyond a red colour with the acetate bath. He asks what toning bath will yield a browner tone.—There is always a difficulty in toning paper prepared in this way, whatever bath be employed. The best plan is to immerse the prints in a weak solution of common washing soda, say a crystal the size of a walnut in three or four pints of water, prior to toning. When this is done the prints are usually more amenable to the toning solution.

AN OLD PRINTER complains of mealiness and blue staining in his prints. Notwithstanding that he used different samples of paper, new toning baths made with different chemicals, and ringing the changes in various ways, the evil still exists. From the above information it would appear that the trouble arises solely from something in the manipulation. But what, it is impossible for us to indicate unless we saw the work in progress. One or two of the prints enclosed appear to have been toned in too strong a light, hence the whites have become degraded. May not too strong a light during the washing and toning of the prints really be at the root of the evil?

DATIVES writes: "I should feel obliged if you would kindly give me a few hints on carbon double transfer from flexible support to opal. I have been using gelatine rendered partly insoluble with chrome alum for immersing the opal before bringing the transfer paper into contact with it. After squeezing very firmly, I allowed the opal and support to dry, but when I attempted to separate the two some portions of the film refused to leave the support. I used the Autotype waxing compound—resin, three drachms; beeswax, one drachm; turpentine, ten ounces—for the support. Kindly tell me the proper proportion of gelatine and chrome alum to be used for the last transfer to the opal."—The difficulty appears to be due to the support being insufficiently waxed. Sometimes, however, if the print is over printed, and very hot water used in the development, there is a difficulty in transferring, particularly if the support is imperfectly waxed. In future, after treating the support with wax allow it to stand for half an hour or so and then wax it again; you will then, doubtless, experience no further trouble. For transfer solution: Nelson's photographic gelatine, one ounce; water, half a pint; dissolve, and add eighteen grains of chrome alum in two ounces of warm water.

RECEIVED.—No. 1, *Ueber Aehnlichkeit*, Weimar: Verlag der Deutschen Photographen-Zeitung (K. Schlier).

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—Technical meeting, Tuesday, April 23, at 5A, Pall Mall East, at eight p.m.

At the annual meeting of the shareholders of Messrs. Norman, May & Co. (Limited), Malvern and Cheltenham, held on Tuesday, the 9th instant, a dividend of seventeen and a half per cent. for the year ending December 31, 1888, was declared.

TRIP TO THE CRYSTAL PALACE.—The Hastings Photographic Society enjoy themselves.—On Wednesday, April 11, twenty-seven members of the above Society and friends availed themselves of the arrangements made with the London, Brighton, and South Coast Railway, to visit the Photographic Exhibition at the Crystal Palace. The train left Hastings at half-past eight. A pleasant ride, so shortened by congenial conversation that the daily newspapers were entirely neglected, brought the party to East Croydon, where a change was made into the train for the Palace. Arriving there about eleven o'clock, a thoroughly enjoyable day was spent in examining the large and wonderful collection of photographic apparatus, and criticising the equally large exhibition of photographic art productions. Most of the party returned by the seven o'clock train, arriving at Hastings at a quarter to ten p.m.

No. 1512. VOL. XXXVI.—APRIL 26, 1889.

PATENTS IN PHOTOGRAPHY.

THE attitude of the public towards a patentee is not unfrequently both hostile and unjust. This, in some instances, arises from thoughtlessness and non-recognition of the fact that a man has a right of property in his brain labour, a right entitled to be respected whether the outcome of the labour be a book, a work of art, or a mechanical invention. A patentee gives to the world something it did not previously possess, and thereby becomes a benefactor to his fellow-men.

In photography we honour and are grateful to the man who gives a present to his fellows of the result of his investigations and experiments, and very much that we possess has been acquired in this way; but are we to say that, because this is so, we can reasonably expect that all are to do the same? Were this the case, and were thanks—and sometimes not even that—all that was to be placed in the scale against the unremitting toil of months, nay, often years, accompanied by weighty pecuniary expenditure, how many inventions from which mankind are now receiving benefit might have been allowed to remain sealed up? It is only right and just that the inventor should receive remuneration commensurate to the value of that which he discloses. Of two men, the one who makes an important discovery and works it *sub silentio* and for his own benefit, allowing his secret, perhaps, to die with him; and on the other hand, the other who imparts to the Government and to the world the fullest account and most ample details of his discovery on the cheap terms that he himself shall have a monopoly of it for a limited term (and for which concession he has, by the way, to pay somewhat smartly), after which it becomes public property—of these two, which is the real benefactor?

The principles upon which patents are granted are most just and equitable. The Government says in effect to the inventor, Your invention, which is to benefit the public, will be secured to you for a term of years on payment of a fee, and upon condition that you divulge everything connected therewith, so as to enable the public to utilise it to the fullest extent on the termination of the period for which we will grant you a monopoly; but, it adds, this protection will only be granted if you make a "clean breast" of it. And this having been complied with, the patent is granted. It goes without saying that the invention must not only be useful, but must also be novel, in the sense of its not having been previously known by the public.

An infinitely greater number of photographic patents are shipwrecked by want of novelty than by lack of utility. An agent entrusted with the taking out of a patent for an invention, when making the necessary search in order to discover

whether it has not been anticipated, usually confines this search for the most part to the records of previous patents, instead of wading through the literature appertaining to the subject in hand, and we are aware of several patents that have had to be abandoned because of prior publication in these pages. It is held to be publication of a nature sufficient to invalidate a patent if a discovery of a similar nature has been divulged, not only before a photographic society, but before seven individuals, a fact which should render inventors chary of saying too much previous to an application for protection having been made.

As to utility, this constitutes a theme on which even "doctors" differ. We know of one photographic invention for which the patent authorities declined to grant a patent on the ground of its not being of sufficient importance, while a few years afterwards a patent was obtained by another inventor for precisely the same thing. As this happened when the custom prevailed of printing all provisional specifications, whether they were completed or not, it follows that the publication in this way of the former invalidates the latter patent. The invention here alluded to had reference to applying the adhesive paste to the mount instead of to the print. Again, inventions which are passed by the patent authorities are not unfrequently set aside by the judge, as being of too little importance, when a case of infringement comes to be tried. Of this class was Edwards's registering frame for double printing, a really useful contrivance, although Vice-Chancellor Malins held a different opinion. A patent to be good must be separated from anything previously known by a sufficiently broad line of demarcation.

We have hinted that the attitude of the public towards the patentee is somewhat hostile. This feeling is based upon the restriction in the manufacture of the new invention. If the antagonistic feeling arises from the fact of the alleged invention being already known, even if not brought prominently before the public, the objector has no real cause of complaint, because in that case the patent is invalid, although the previous knowledge of it by any one individual alone who works it in secret will not affect its validity.

While this is well understood, there is a certain excuse for the feeling of indignation that prevails when paltry, frivolous modifications or applications of things previously well known are sought to be secured by patent; and of this class there are, unfortunately, not a few in photography. Many of these would not successfully pass the test of a law-suit, were such brought to try their validity; but only an extremely limited number of them are carried beyond the provisional stage, after which they, so far as they are known, become public property.

It is quite astonishing to look over the patent list published weekly in these columns, and compare the numbers of "patents applied for" with those of them which are subsequently and before the year is out recorded in the patent books as having been "abandoned." Taking up the latest weekly issue of the *Patent Office Journal*, we find on one page, selected at random, that of twelve applications thereon recorded no fewer than five are notified as "abandoned." This refers to patents in general, but were a similar comparison made and confined to such as relate to photography, the proportion of those not proceeded with would probably be found to be much greater.

COMBINING TWO OR MORE NEGATIVES.

It frequently happens in taking a photograph that it would be much improved, as a picture, if it were possible to obtain a little more subject than the plate will include with the appliances at hand. For example, in taking a landscape on a whole-plate the amount of subject included vertically may be just eight, while that laterally would be infinitely better if it could be extended to ten or more inches. How is the difficulty to be overcome? One plan will at once suggest itself, namely, to take the picture with a lens including a wider angle of view. But this would not fulfil the conditions, even if such a lens were at hand, inasmuch as then more foreground and sky would be obtained than is wanted. If these were trimmed off in mounting, the picture would then be generally on a more diminutive scale than that desired.

The plan, under the above conditions, is to take the picture on two negatives and combine it afterwards. This is frequently done by making a print from each of the negatives and then joining them in the mounting—a very unsatisfactory proceeding at best, for it is seldom indeed that two or more prints can be so neatly united as not to show conspicuously in the finished result. Moreover, it is exceedingly difficult, simple though it seems, to produce prints from different negatives of precisely the same tone, and the slightest difference in this respect always renders the junctions the more pronounced. It is true that in dexterous hands it is possible to obtain the two prints on the same sheet of paper by double printing, so that the junction is almost, or quite, imperceptible. But to accomplish this requires an amount of skill and practice which the average amateur does not possess.

The best means for effecting the end is, undoubtedly, to combine the negatives themselves, be they two or more, into one, so that the print is secured on the same piece of paper at a single printing. Now if, in the first instance, flexible negatives be taken, such, for example, as those obtained with stripping films, the thing becomes simple enough, provided, of course, a few simple precautions be observed at the time of taking. For our present purpose we shall suppose that the stripping films are employed, and will, therefore, give the details as regards the combination, because the same principle is involved, whatever other method be followed.

In taking the different negatives, on no account must the position of the camera be altered between the exposures, otherwise than by rotating it horizontally on the stand. When arranging the camera it should be decided at which point the juncture is to be made. This should, if possible, be at some part where there is but little sky showing, as it is always much easier to hide joins in the darker than in the lighter portions of the picture. In deciding the amount of subject in each of the negatives, a good margin should be allowed for the joining,

inasmuch as if the portions to be united fall near the edges of the plates the difficulties are increased considerably. It is seldom that the film is really uniform near the edges of a dry plate. Furthermore, the illumination falls off towards the margin of the field with most lenses. Therefore, if the full amount of subject which would be included by two negatives be required, it will be found more advantageous to take three. Two junctions under favourable conditions are far more easily hidden than one under conditions less propitious.

The exposure for the different negatives must be identical as regards time, and the development must be conducted so as to secure them, as nearly as possible, of equal density. In this portion of the work there is nothing out of the ordinary course of procedure necessary beyond the precautions just indicated. As we are writing on the supposition that flexible films are employed, we will now assume that the operations have been completed and that the negatives—two or more—are ready for uniting, which we now proceed to do.

A glass plate, a little larger than the picture when finished, is placed on a retouching desk or in front of a window, so that a good light is seen through it. Next, one of the negatives is taken and adjusted in position upon it, and each of the edges, except that to be joined, secured to the glass with strips of gum paper. The second negative is then put into position, the duplicate and now overlapping portions in the two negatives serving as a guide to accurate adjustment. The edges of this negative are then firmly fixed with gum paper. The only thing that remains to be done is to cut through the overlaying portions of the negatives with a sharp penknife, making one clean cut and remove the liberated pieces. The edges of the negative will now fit exactly into each other, and if the cuts are neatly made the juncture will be quite imperceptible. In no case should the junction be made in a direct line through the picture, but in an irregular course, and, if possible, through foliage or buildings.

In the foregoing it has been assumed that flexible negatives are taken to begin with, but it may frequently occur that glass ones have to be utilised, then it follows that some modification of the method just described must necessarily be adopted. With glass negatives the films can be removed from the plate and transformed into a flexible negative by Plener's method with hydrofluoric acid. But here there is some little risk of the films, when removed, expanding, and that unequally. This, of course, would be fatal to a successful junction. But by employing Mr. Pumphrey's modification of the fluorine acid method this risk is reduced to a minimum. This modification is described on page 495 of our *ALMANAC* for the present year.

With valuable negatives, or such as cannot be easily replaced, it is, perhaps, better on the whole not to attempt to strip them from the glass unless the work be undertaken by experienced hands, but to proceed by way of reproduction. Details of this system must be deferred to a future article.

THE DEVELOPMENT OF TRANSPARENCIES.

In the treatment of wet collodion plates the character of the deposit forming the image can be greatly modified, so far as fineness is concerned, by varying the mode of development, because the metal forming that image is derived from the developing solution itself, and is deposited in a coarser or finer state in proportion as the rapidity and other conditions of development are varied.

But when we turn to dry plates and alkaline development the circumstances are altogether changed, since the image is formed by the reduction of the metal already contained in the sensitive film. It can, therefore, be readily understood that the fineness of the deposit will, in these circumstances, be mainly dependent upon the state of division of the particles of silver bromide formed in the emulsion, hence, in development, our power of influencing the character of the image for fineness is limited. It is true that in some cases of rapid or forced development, in which very strongly alkaline solutions are employed, an image of considerable coarseness is frequently produced upon plates not usually remarkable in that respect, but this has been set down to the reduction of certain coarser particles of bromide lying in the under stratum of the film, and not generally reached by a developer of ordinary strength.

So far then as an extremely fine deposit is concerned, where this characteristic is especially desired, the best, if not the only thing to do, is to select a plate that is known to possess a film of that quality. Many of the specially made commercial lantern plates, though not all, present this feature, which usually accompanies a film of only moderate rapidity, and such plates are to be preferred on all grounds to the more rapid kinds for transparency work. It by no means follows that a slow plate necessarily gives a fine image any more than, as many suppose, that an extremely rapid plate must give a coarse deposit; the rule can only be accepted as a general one. But in our own case, given two plates identical in character as regards deposit, but of different degrees of rapidity, we should for transparency purposes prefer the slower, because in ninety-nine cases out of a hundred, it will give a better result with the same amount of trouble.

Starting on the assumption, then, that the fineness of the image is a matter over which we have practically no control in development, we may confine our attention to securing the most perfect gradation possible from deepest shadows to highest lights, placing the colour or tone of the picture as a subsidiary, although still important consideration. We have already said, with regard to the gradation of a perfect transparency, that its range should extend from perfect clearness—"bare glass" as it is technically called—in the very highest lights to a depth in the strongest shadows, which, while sufficient to give force and value to the picture, falls still far short of opacity. Where anything approaching opacity in the shadows of a transparency is reached, not only is the general character of the picture heavy, but the gradations become imperfect since the half tints and lighter shadows begin to merge into adjacent tints. It is impossible to give any definite rule as a guide to the proper degree of density, for this will vary not only with the subject, but also with the purpose to which the transparency is to be put, while personal or individual taste will perhaps prove the most variable condition of all. In this, as in most other affairs, experience must be the principal guide, but certain chief rules may be held in view. These are, that lantern slides as a rule require the least density, though this may vary in proportion to the strength of the light with which they are to be employed, the oxyhydrogen light requiring a more vigorous picture than an oil lamp. Stereoscopic transparencies may have more strength than an average lantern slide, but still delicacy rather than vigour should be the aim, care being of course taken to secure sufficient force to give value to the deepest shadows and provide harmonious contrast. Greater density is required in transparencies for ordinary decorative purposes, for hanging or glazing in windows and screens, or

in lamp shades, and the strength should increase with the size in order to give the requisite boldness of effect. Thus a degree of density that would give a perfect result for a picture of, say, quarter-plate size, would look weak and flat if repeated on the scale of 12×10 or 15×12 , while what made a harmonious result in the above sizes would prove wholly unsuitable for smaller work.

It is the securing gradation which forms the chief art of development in transparency work, more, perhaps, even than in the case of negatives; the mere production of clear lights (or shadows) and pleasing tones forming technical details which present no difficulty to the practised worker. We speak, of course, within the limits of the possibilities of each kind of plate, for clearly no plate with which we are at present acquainted possesses the capability of giving an unlimited range of tones at will, and few gelatine plates will give the utmost clearness of lights desirable in a lantern slide.

In securing the proper range of tints, experts differ in the methods they adopt, some applying a developer of full strength, which brings up the picture rapidly to full strength in, so to say, a single operation; while others work on a gradual or "tentative" system, employing a weak developer well restrained, and strengthening it gradually as the necessity arises. There is much to be said both for and against both methods, and it would be unwise to adopt either one or the other without properly considering the why and wherefore.

For instance, the first plan, the "straightaway" method, recommends itself on account of its apparent simplicity, and the rapidity with which the operation is performed. The very rapidity is often an important element with some kinds of gelatine plates, as there is less chance of staining the film, and undoubtedly, when time is an object, this will be preferred to the slower process. But obviously, in order to be successful in the principal object—the production of a precisely correct gradation from clear glass to just sufficient density—it is necessary to hit the exact exposure with extreme accuracy; in fact, with this method of development, nearly everything depends upon the accuracy of exposure, the development being, comparatively speaking, a cut-and-dried operation. Hence, except with plates that are thoroughly well known, an illuminant that is completely under control, and negatives themselves of perfect gradation and well-judged density, this method is not likely to give generally satisfactory results except in thoroughly experienced hands. It becomes proportionately more difficult of application with the more rapid kinds of plates, though with the slower descriptions comparatively easy.

Latitude there is practically none when this plan is adopted, for the solution first applied being of the full strength that can be safely applied, it is of little avail to add further alkali in the case of under exposure, as either that course or the mere prolongation of the application would be almost certain to result in the degradation of the lights, if not in general fog. In the case of over exposure the energy of the solution might certainly be checked by the use of a liberal addition of soluble bromide, but as this acts more energetically on the least-exposed portions of a film, the lights and shadows would suffer disproportionately, and the general result would tend towards heaviness and excess of contrast instead of correct gradation.

All things considered, we are inclined to look upon the tentative method as the preferable one, in spite of the greater length of time consumed in the operation. That seems to be the chief objection to its use, though some kinds of gelatine

employed in the formation of films will not stand the prolonged application of pyro solution, however weak or restrained, or whether protected by sulphite or not. When plates are met with possessing this bad quality, the tentative method of development will therefore have to be relinquished or considerably modified.

On the other hand, this method enables us to utilise to the fullest the advantages of such a degree of latitude as exists both in exposure and development. This will be especially valuable to those who only practise this kind of work at irregular intervals, and who are consequently comparatively unfamiliar with the power of their light, and are perhaps not intimately acquainted with the peculiarities of their plates. The power of varying the development is also useful in dealing with negatives of irregular or incorrect gradation, whether excessively dense, too thin, or presenting too much or too little contrast. Such may frequently be "dodged" into giving a fairly good result when developed in the gradual manner, but would prove hopeless failures with the "straightaway" method.

On the whole, therefore, we give the preference to this latter plan, especially in the case of those who have had but little experience in the work. In a future article we shall give the full details of both methods as applied to pyro, hydroquinone, and ferrous oxalate.

A CORRESPONDENT has lately suggested, *apropos* of paintings with a photographic basis, that it might be an excellent plan to prepare the photograph for painting upon by pasting or glueing over its surface a sheet of the fine unvarnished tracing paper, more like superior "tissue paper," which is sold by some dealers, so that all colours employed would be removed from actual contact with the chemically produced photographic image underneath, yet would have presented to them a suitable surface to work upon. Those of our readers who are familiar with artistic processes will best know what value to attach to the suggestion. From a chemical standpoint, if it be only granted that a photograph must be inimical to the permanency of the pigments laid upon it, there is no doubt that when once the painting was dry no mutual chemical action could occur.

This is no light question to many professional photographers who are in the habit of employing artist painters of very considerable skill. We now refer not to the low-priced monstrosities which have invaded the land like a pestilence, and almost destroyed the belief in the public mind that a combination of photography and painting of some degree of merit might be obtained, but to the highest class of this kind of work which is obtainable.

We have had the opportunity of examining a large number of portraits so painted upon silver, upon carbon, upon platiotype prints, and we have come to the conclusion that the durability of such pictures is by no means a matter of the photograph only; it is closely interwoven with questions of mediums employed and particular colours selected.

We by no means wish to raise a discussion upon the special suitability of any particular kind of photograph chosen to work upon, for common consent has it that silver prints are unsuitable, and carbon and platinum are by their advocates deemed perfect. But we do have to say that as we write there is before us a very beautifully executed water-colour upon a silver print, executed over thirty years ago, which has faded little more than an average water-colour would have done in the same time. At the same moment we turn to another equally well-painted portrait upon carbon, which, painted about fourteen years ago, is faded to a great extent.

Not for a moment must the inference be drawn from these facts that silver is a better base than carbon, for the reverse is incontestably

the case. It is here clearly a case of badly selected colours, or of a chemically impure medium used with the colours. For proof of this, we have noted that where some flesh tints had been introduced, painted-in upon the paper itself where no photograph lay, the fading was equally conspicuous, as upon those parts where the carbon print lay underneath the paint.

THE remedy is obvious, though one that will not always be taken. It is to change the scheme of colours chosen. There are many fairly permanent pigments to be bought with a reputation ready made; there are others known to be fugacious, but which yet, because of their cheapness, or fatal facility of working, are not banished from the palette of some artists. To call attention to these various points should be sufficient to the conscientious.

THOUGH of less importance than the Perseids of August, or the Leonids of November, the Lyrids, as the "shooting stars" usually seen at this time of the year are termed, are sufficiently numerous to occupy a prominent place in astronomical annals, and last Sunday or Monday large numbers of observers would be at work counting and noting the position of flight of the meteors then visible. When the number to be observed are large, it is scarcely possible for a single observer to do this correctly. We draw attention to the matter to point out how easily photography would give important help, even without any clockwork arrangements. A portrait lens would embrace almost the whole of the probable field of such star showers, and, we should imagine, would, with quick plates, register a very large proportion of the meteors seen, and give their direction infinitely better than any personal observations. A fresh plate, exposed at intervals not too far apart, would give the position by the fixed stars, and which would show as streaks instead of dots; indeed, a series of such observations made under systematic arrangements by observers at various parts of the kingdom would be of great value in another way. Such parallax would be exhibited, that a very close estimate could be formed of the actual distance from the earth of these celestial visitants.

WE had thought that the theory of actinism being confined to the violet part of the spectrum was a long-exploded fallacy, but in reviewing a recently published work upon light and heat, *Nature* draws attention to this old fancy being adopted in the book, saying, "The idea that the actinic rays are confined to the violet part of the spectrum is rather old-fashioned, and is scarcely likely to be credited by a student who may have happened to experiment in the direction of orthochromatic photography." This, of course, is quite true; but it has long since been pointed out that decomposition under the action of light was rather a function of the particular substance than of a particular ray of light.

PHOTOGRAPHERS themselves, however, are as often ignorant of the physical properties of light as painter artists are of colour; witness the cloud monstrosities often perpetrated by the former and the meteorological impossibilities of the latter, who often, if they cared to do so, might take a lesson from photographers. An advantageous step in an educational direction in regard to the latter is about to be taken at the Bedford College for ladies, the art students of which are having arranged for them a series of lectures on light and colour by the Professor of Physics, M. Wornack. It goes without saying, that in order to obtain a proper knowledge of art the physics of light and colour should be studied.

ON THINGS IN GENERAL.

I MUST congratulate the proprietors of THE BRITISH JOURNAL OF PHOTOGRAPHY upon the latest step they have taken in popularising photography—by reducing the price of its leading literary organ. It is to be hoped that this will lead to such an increase of subscribers as to entail no real loss; though I may say that it is only those who are familiar with newspaper enterprises that can understand how much is involved in such a pecuniary change. It is very interesting to compare the JOURNAL of the present day with the Liverpool-

Manchester JOURNAL of, I am afraid to say, how many decades ago? To many modern photographers it would be almost as Greek to the unlearned. Yet in those early days, and later, up to the introduction of gelatine, what beautiful negatives were produced! We had not the rapidity of modern plates, but there were, instead, a richness, a depth of shadow, a combination of vigour and softness that is rarely seen nowadays in the negatives on "ready-made plates." I have heard of one amateur, whose work has always been of the highest class, and who had fought all the battle of processes himself, being so disgusted with the ease of present-day photography as to contemplate flinging it up entirely. I do not know if he will carry out his purpose, for it is a fascinating pursuit to those who have once mastered the processes—the "operation of chemistry, more or less directed by taste," as Mr. Brett, A.R.A., terms it.

Those who have not read it should by all means peruse the shle paper by that artist, read at the Camera Club Conference and reported in the April 5 issue of this JOURNAL. It gives in a few pithy sentences an excellent epitome of what it is desirable for an artist to learn and to cultivate to attain to a sufficient amount of skill; but it is touched with the usual inconsequential dicta, and defective logic of those painters who will not permit the association of fine art and photography. Thus, we are told, "It is only after long training that the observing faculty becomes so keen and active that a good photograph can be confidently expected. Most operators never outlive the fluking stage. The cultivation of this faculty is no simple matter. . . . You have to consider your subject, first, as a group of masses of light and dark; then you think of the arrangement of line caused by the coincidence of the boundaries of these masses; then you have to study the distribution of the accent or emphasis in both elements; and until you have become in this way a trained analyst, all your endeavours will be empirical, or shots in the dark. . . . practice with the camera will compel him to learn composition and *chiaroscuro*," &c. &c. How could a better epitome of an artist painter's educational needs than is here given be portrayed? It is lucid and to the point; yet if a photographer to whom this advice is given, be it observed, cultivate his faculties to the requisite extent, he can only exhibit "good taste," not art, in his works. I ask, is not this toying with words, especially when we find the same writer admitting "there is another resource of pictorial art available also to the photographer, though only to a limited extent, and that is sentiment?" Sentiment, composition, light and shade, *chiaroscuro*, may be displayed, and yet nothing but "taste" is shown. Why cannot the painters say boldly, "There are possibilities of flights of genius and capabilities of expression and of *technique* in painting that photography cannot dream of; but, to a limited extent, photographs may exhibit qualities of fine art sufficient to command both respect and admiration, when executed by hands directed by a trained and educated mind?" For this is true, and they will have to admit it sooner or later.

In the same week's JOURNAL I read an article on lenses by an American writer, in which he speaks in terms of respect of an English optician, Mr. Wenham, whose inventions, applied to the microscope, have done more to popularise it than all others put together—his name is on almost every microscopist's lips. I see also in the journals of the day a list of names far less familiar who are to be decorated with the blue ribbon of science—the title of F.R.S. I make bold to say that scarcely one of them is better entitled to the distinction than the gentleman named; yet he is no F.R.S. Why?

There can be no doubt that the majority at the Photographic Society's meeting recommending the grant of medals at future exhibitions represents the feeling of photographers at large upon this question. The next exhibition, if I mistake not, will show by its quality that medals do help to bring about the exhibition of good work, and thus improve the general level by showing what can be done. I should like to ask one question. "What about the unfortunate exhibitors of last year; may not they send their works again on the chance of receiving a medal?" The chance ought to be offered, and then there would be a fine opportunity for the hanging committee; they would be compelled to reject a large number of works, and thus improve the whole tone of the show. I present the Society with these hints.

Those who have not read Mr. Lionel Clark's letter on platinotype printing should do so. It is an excellently well thought-out com-

munication, with a thoroughly practical ring, and, I think, bears promise of a really practical process. Should it in practice be found to give results equal to the old platinotype, it would revolutionise that class of printing, and would also have the advantage of permitting any kind of paper to be used for obtaining an image upon. The Platinotype Company have done a great deal in the direction of supplying papers of various kinds and surfaces, but Mr. Clark's method would give us all surfaces from rough Whitman's paper downwards.

There are some processes which, at a first glance, strike us as good and practical, while others have just the reverse effect. Mr. Clark's letter belongs to the first; in the second I should place the developer whose formula is given in "Foreign Notes and News," page 270 of this JOURNAL. Given in full (as used where frilling might be anticipated), the mixture for developing consists of pyro, sulphite of soda, oxalic acid, carbonate of soda, yellow prussiate of potash, metabisulphite of potash, bichloride of mercury, and water!

At the London and Provincial Photographic Association an interesting discussion lately took place upon the topic of cloud negatives, and attention was called to an article in which it was stated that dwellers in towns could not obtain appropriate negatives because of having to tilt the camera to an unsuitable portion of the sky. Now there is a great deal of absurdity in this very common idea. Let any one go to any exhibition of photographs and ascertain how many of them have clouds down to the horizon, and how many at such altitudes in the sky—showing above the other objects, houses or trees, &c., as to be well above the angular distance from the horizon of the chimney-pots—as a cloud negative taken from an attic in an ordinary dwelling house. The latter would be five to one of the former.

FREE LANCER.

ECHOES.

"Good old printer!" I give you the credit, and not Mr. D. Bachrach, jun., of having added one more to my list of photographic chemicals. "Yellow prussic of potash" looks well, but what is it in less scientific terms? I must, however, do Mr. Bachrach himself the honour of attributing to him the discovery of a new use for bichloride of mercury, and of making it exhibit in a character I should not have given to it.

In brief words, to prevent frilling in summer-time he recommends the addition of bichloride of mercury to the pyro and soda developer, in order to "harden the film and prevent decomposition." He naively remarks that it is "the best thing to use, being without any effect on the action of the developer." Quite so! But what about the action of the developer upon it? Perhaps, however, as it is only used in the proportion of ten grains to each ounce of *solid* pyro, no very visible effect will be produced. But then—another "but"—what about its *hardening action* when the ten grains are diffused throughout perhaps a couple of gallons of developer? However, great discoveries do not always strike the world at once.

I do not quite know why the recent performance of M. Bloch, in exhibiting to a whole class, by means of the lantern, the development of a plate, should be designated an "ingenious arrangement," since it is acknowledged to have been well known to old collodion workers. From the mention of "red" as the colour of the developing trough, I imagine the novelty, if any, consists in the application of the arrangement to gelatine plates; but, if so, what am I to think of the developer mentioned as being used in the experiment? This is said to have been composed of pyrogallol, gallic, and acetic acids, with "a few drops" of nitrate of silver—acid development in fact, which is certainly not usual with gelatine.

In the same column of foreign news I find mention of a new method of giving "a good brown colour" to platinum prints, consisting in the addition to the developing solution of more or less mercuric chloride, according to the tone desired. Of course the modification in colour is produced by the substitution of a certain quantity of mercury for platinum in the formation of the image. What Mr. Willis and other supporters of permanency in photographic prints may think of the "improvement," I, of course, do not know, but I can form a good guess. I myself should class M. Tueschala-Signa's process along with a "new" method it was attempted to introduce

many years ago for toning silver prints. In this, chloride of gold was partly replaced by chloride of copper, and very pretty tones were produced, but, like the "good brown colour" of the new platinum-mercury print, they were scarcely permanent, since the hypo removed every trace of the copper tone.

There is plenty of room for the introduction of improvements in developing dishes, and the utilisation of thin enamelled steel seems to promise to be a step in the right direction, since it will combine strength and rigidity, especially in large sizes, with lightness. But it is not encouraging to find that one of the "special features" claimed for the new dish by the makers is, that if dropped on the floor it don't break, because it is apt to make one think they have misunderstood the use of developing dishes generally. We don't purchase these to throw about, but to use carefully, and if the makers have gone equally astray in other important points, perhaps it will be wiser to stick to glass, ebonite, or porcelain.

This is unmistakably an age for giving or offering prizes for any and everything, but it is seldom we find so curious a result chronicled as that in connexion with the Gaillard prize, in France. It seems M. Gaillard offered a prize of five hundred francs for an original process for the rapid production of positives, leaving the adjudication in the hands of the Photographic Society of France. From the official report just made public, it appears there was one solitary competitor—if he can be so called—who put forward the gelatine bromide process, which he neither "invented" nor "discovered," and which could not, therefore, in his case, be original. However, though the committee could not award him the prize, they gave him just three-fifths of it as "an encouragement." It reminds me of a somewhat similar award made in this country some years ago, when the committee reported that they did not consider any of the competing processes worth the prize, but as it had to be awarded they had given it to the "least bad." This was, at any rate, a more straightforward way than keeping back a part of the money.

It is only a few weeks since I had to allude to the suggestion of automatic development, and now the matter seems to have cropped up again in a slightly different form. I read in the report of the Photographic Society of France that M. Tondeur has been experimenting with self-developing plates, with results that are sufficiently noteworthy to be considered in connexion with the general subject. The method adopted was to saturate the film with developing solution before exposure, and the experimentalist proceeds to say that if sufficient exposure be given the negative is fully developed during exposure; if not sufficiently exposed it must be left until the details appear.

I think these facts will bear a good deal of looking into, though I must confess there is a little ambiguity about them, especially with regard to what constitutes a proper exposure. I don't think, at any rate, that existing "exposure tables" will be of much use. Thus, if sufficiently exposed, development proceeds simultaneously, and is complete with the exposure. Hydroquinone is the developer recommended, and this I hear on all sides is very slow in its action. I have heard of an amateur, of sabbatarian views, who places his plates, exposed on Saturday afternoon, to "soak" on Saturday evening, and removes them from the developer before starting for business on Monday morning. If this be anything like the period occupied in developing M. Tondeur's images, what must a sufficient exposure be?

But, on the other hand, if a plate is not "sufficiently exposed," i.e., what we should, under ordinary circumstances, call "under exposed," it is only necessary to leave it until "all the details have been brought out," or, in other words, as it seems to me, there is no such thing as under exposure, or, for that matter, over exposure either. I am all the more willing to accept this view as correct, because it is only under such conditions that automatic development would be possible; indeed, it is only those who are utterly incompetent to judge an exposure who would dream of such an absurdity. We have heard of uneducated men writing poems and painting pictures while unconscious or asleep, but their excuse has always been that they were under psychic or some other influence. But, judging from what I have seen of the artistic or even technical qualities of so-called "spirit photographs," I question whether the automatic development amateur will improve his pictures by taking on "psychic force" as chief assistant.

The same gentleman introduced to the society a "minocle," or eye-glass, possessing wonderful properties, if we are correctly informed. By the way, I know what an eye-glass is, and I have heard the term "monocle," or "monocular," but "minocle" is new. However, the instrument in this case consists of a disc of ebonite pierced in the centre with a very small hole, and is to be employed in order to judge the colour of the light and its actinism when out photographing. In fact, it forms the long-wanted reliable actinometer. Thus, when the light is really of bad quality, though apparently bright, upon applying the little instrument to the eye the light takes a yellowish tint, and the faces of the passers-by a red colour. Again, the inventor has been surprised on an apparently dull morning to find surrounding objects, when viewed through his "monocle," assume a "bluish white tint," suggestive of actinism, and a very short exposure followed by a magnificent negative has proved the prognostication to have been accurate.

I think it is possible that imagination may have assisted very materially in establishing a certain faith in what may be, undoubtedly, a useful little contrivance, but I think also that the variations in colour must be confined to the imagination and not allowed to tinge surrounding objects. The aperture in the ebonite disc will have to be so extremely small, if it is to produce any breaking up of the rays of light and assist in analysing their colour, that very little chance would remain of distinguishing adjacent objects. But if sufficiently large to permit objects to be viewed without the disturbing influence of extraneous light falling on the eye, it is very possible that a better judgment can be formed of the relative value of the illumination of different subjects. Many years ago it was customary to employ a piece of yellow glass for a similar purpose. If a landscape be viewed through such a piece of glass by absorbing a portion of the blue and violet rays, the darker parts of the subject are intensified, and a better idea can be formed of the contrasts of the picture and the length of exposure desirable. But, after all, it must be "judgment" that does the work, for I verily believe an automatic actinometer is as impossible as automatic development.

M. Schaeffner's new varnish for negatives looks and sounds very well in description, but there is nothing about it that does not agree with the ordinary aqueous shellac solution. It is transparent, can be applied to the wet negative and without heat, it takes the pencil, it permeates the pores of the film, and is not confined to the surface, all of which descriptions apply perfectly to shellac dissolved in aqueous solution of borax. But the latter has not "the advantage of never cracking when dry." It is easily applied, soaks into the gelatine film, and gives a most delightfully even surface. But if heated or moistened after drying, it is "all up" with the negative. It cracks all over, and, what is worse, the cracks cannot be obliterated by any kind of treatment that I have tried.

JUNIUS.

AN EASY AND ECONOMICAL METHOD OF MAKING LANTERN PLATES.

NO. II.—PREPARING THE EMULSION.

WE shall require an earthenware jar or tin with a cover, about six inches in diameter and seven or eight inches high, a hot water thermometer, a clean four-ounce bottle, and a kettle of boiling water.

We will suppose that eight ounces of emulsion are required, which will be sufficient to coat six to seven dozen lantern plates. Weigh and measure out carefully the following (hy-the-by, it is better to put a piece of clean paper of equal size and weight in each pan of the scale):—

No. 1.

Bromide of potassium	18 grains.
Gelatine	2 drachms.
Water	1½ ounces.

No. 2.

Nitrate of silver	24 grains.
Water	2 ounces.

No. 3.

Iodide of potassium	1 grain.
Water	½ ounce.

It is a good plan to keep the iodide of potassium in a ten per cent. solution, and instead of attempting to weigh one grain use ten minims of the solution.

Put the bromide of potassium into a clean, half pint drinking glass, or similar glass vessel, and add the one and a half ounces of water; when thoroughly dissolved, put the gelatine in and let it thoroughly swell. I have been using Coignet's silver medal gelatine, and find that it gives a clear film, but I expect that Heinrich's or Simeon's will do as well. Fill the jar or tin with the hot water from the kettle to the depth of about three inches, and then plunge the glass containing the gelatine, &c., into it two or three times, to avoid it cracking by the heat, then leave it for the gelatine to dissolve; assist this by stirring with a glass rod, or a strip of glass about three-quarters of an inch wide.

After the gelatine appears thoroughly dissolved, keep it (the gelatine solution) at a temperature of about 90° for ten minutes; stir it well every few minutes.

While the gelatine is dissolving put the nitrate of silver into the four-ounce bottle and add two ounces of distilled water (it is better to use distilled water for all the solutions; it is cheap enough). When the silver is dissolved add ammonia (equal parts of ammonia 880 and water) a few drops at a time, just sufficient to dissolve the oxide of silver first formed. Shake the bottle between each addition: have a good, clean cork to the bottle. Stand the bottle in the jar of hot water to slightly warm the solution. The rest of the operations will have to be done in the dark room, or with a non-actinic light.

Stir the gelatine and bromide solution in the glass, and at the same time slowly pour into it the nitrate of silver solution; then add the iodide of potassium and water and stir well. We shall now obtain an emulsion with the particles of silver bromide in a very fine state of division, and if we put a drop or two of the emulsion on a strip of glass and find, on looking through it at a candle or gas jet, that it appears of a bright ruby colour, the operations have been correctly carried out.

Now get the water in the jar to a temperature of about 95°, not more than 100°, stand the glass containing the emulsion in it, put on the cover, and a teapot coxy or cloth over all for twenty minutes. It is as well, however, to stir it up once or twice during that time, and see that the water does not get below 90°.

At the end of twenty minutes pour the emulsion into a dish (a soup plate will do very well), and as it sets break it up into small pieces to allow a greater surface to be exposed to the cool air. This can be done with a small strip of glass. Then put it away in the dark for at least three or four hours, or it can be left until the next evening.

The next operation is to pour about half a pint of distilled water over the broken-up emulsion and stir it up well for five minutes, pour the water off and repeat the operation with some fresh water; after the water is strained off put the emulsion back into the glass (have the glass clean) and remelt it by standing the glass in the jar of hot water at about 110°, when melted add three-quarters of an ounce of alcohol—good colourless methylated will do if procured from a photographic material dealer, but it is hardly safe to depend upon what is obtained from a country chemist. Then add sufficient slightly warm water to the emulsion to make it up to eight ounces in bulk and stir well.

It is a good plan to make a mark on the outside of the glass at eight ounces, and then one has only to pour the water in up to that mark. The emulsion is now ready for filtering and coating the plates.

HERBERT S. STARNES.

HINTS FOR THOSE USING NON-HALATION GROUND GLASS PLATES.

Fixe ground glass, such as used for microscopic focussing, and technically called "smoothed glass," might be used for negative work, and had on reasonable terms from patent plate glass makers. It would give an admirable "tooth" for the *retouching pencil*. Ordinary "sheet glass" might be made with a similar surface by submitting it to the action of weak fluoric acid. If one side only is required, the other side can be protected from the action of the acid by coating it over with tallow or grease.

Printing from negatives so prepared may be quickened by rubbing over the back with the varnish now sold by dealers, called "Protective." I find this article well suited for reviving old faded prints, and protecting brasswork and other metals from rust and corrosion.

JAS. ALEX. FORREST.

PHOTO-MECHANICAL JOTTINGS.

V.

THE REVERSING MIRROR.

NEGATIVES for printing upon zinc or for colotype must be reversed, that is, the image must be in its right position as regards right and left when viewed with the film next the eye, instead of, as in the case

of an ordinary negative, the glass being between the eye and the film. Reversed negatives are obtained (1) by stripping or turning, (2) by exposing through the glass, (3) by using a prism in front or behind the lens, (4) by using a plane mirror in front of or behind the lens.

(1) Stripping or turning the film has been treated of already in one of the earlier "Jottings," also by Mr. W. K. Burton in the issue for March 22. (2) May be at once dismissed, as at best it is only a makeshift method, and never yields perfect results. (3) The prism is too costly a piece of apparatus to ever become generally used, as it has no advantages over the plane mirror, to be obtained at so much less price.

There is a great deal of misconception as to what a reversing mirror is. Some operators trying a piece of ordinary plate glass and finding the resulting image distorted are disgusted. A reversing mirror is a piece of thick plate glass, the surface of which is ground *perfectly flat*, then coated with a film of pure silver, which, taking a high polish, will, when mounted in front of or behind the lens, reflect the image upon the sensitive plate without the slightest trace of distortion.

The size of the mirror must correspond in height with the diameter of the lens, and be a little longer than the diagonal of a square formed by such dimension; for instance, if the diameter of the lens be three inches, the mirror should measure five inches by three. It is not necessary to have a separate mirror for each lens in daily use, as a small lens can be used with a large mirror, but a small mirror, if used with a large lens, will curtail the field.

Reversing mirrors are mounted for use in two ways, viz., in front of the lens and behind it, the latter method being the best, the mirror being protected from extraneous light, also from dust, and from deleterious fumes, besides the box being much smaller and lighter. The base of mirror box should be made square, so that the lens may be used sideways or pointing down—a very useful position in photographing objects unsuitable for fixing on the copying easel.

For silvering these mirrors various formulæ have been given in back volumes of both JOURNAL and ALMANAC, the two best being by Dr. Common and Mr. H. J. Burton. But the best plan is to get a mirror ready silvered from the Autotype Company.

A mirror requires to be managed with care to preserve the silvered surface from damage or tarnish. At the end of each day's work remove from the box and warm slightly in front of the fire (not over a gas stove), then wrap in a piece of fine velvet, also warmed, so as to be free from all traces of damp, wrap this again in a piece of mackintosh, and put away in an air-tight box. By using these precautions, and carefully avoiding touching the surface, a mirror will last for years without re-silvering, an operation which costs sixpence a square inch, the original cost, including mirror and silvering, being one shilling per square inch.

If the surface gets tarnished, the exposure will be prolonged, so the mirror must be re-polished, which is done with a piece of perfectly dry chamois leather, *dry jewellers' rouge*, warming the mirror slightly first and polishing gently and without much pressure. This polishing may be repeated when requisite until the film of silver is worn away. After that the mirror will need re-silvering. W. T. WILKINSON.

CAMERA CLUB CONFERENCE PAPERS.

III.

A COMPARISON OF DEVELOPERS.

By LYONEL CLARK.

NATURAL historians will tell you that whenever a new species is introduced into a new country it begins to multiply and increase to a most alarming extent, but after a few generations nature reasserts her ordinary law, and the new settler settles down to its ordinary and normal rate of increase. In photography we find somewhat of a parallel; the advent of any new process is received with a burst of enthusiasm, its application is universal, and its merits or faults are extolled or condemned with as much exaggeration as any unpopular Government measure in Parliament; and it is not until the first effervescent exuberance of its disciples, or the deep anathemas of its opponents have subsided, that it is possible for the still, small voice of reason to make itself heard, and allow the new comer to be judged strictly on his own merits.

Our latest advent from other climes is quinol; this is, however, not of foreign origin, being no other than an indigenous species, which, under the name of hydroquinone, was first proposed and introduced to the photographic world by our worthy President, and that in this very room, and from the rostrum that I myself am now occupying. On its first introduction, however, it did not meet with any general favour, and it was not until, like old brown sherry, it had made a voyage across the seas and back that it was found good enough for the palate of our connoisseurs.

Slight as was the enthusiasm with which it was first received, its re-

storation to the land of its birth was, however, attended with the most fulsome flattery, and all that exuberance of expletives for which our Gallic brethren are so justly famous. The new developer was to do everything and anything; a very conjurer's bottle, out of which could be got the restrainer of over or the accelerator of under exposure—a very panacea for all our photogenic woes or maladies. One loquacious apostle of hydroquinone, carried away by his own enthusiasm, actually went so far as to style it an "automatic" developer, thus abolishing at one fell swoop all the science and beauty of development, and all the power that chemistry has put into our hands to compensate for its own shortcomings or the unwillingness of nature, and to enable us to relieve our beloved pursuit from the reproach that it is a mere mechanical process.

But these furious atmospheric disturbances have now subsided; we have left the roaring forties of exaggeration for the quiet doldrums of reason, and quinol, as I prefer to call it, is on its trial at the bar of the photographic world. The case was opened by Mr. Swan, in the Photographic Society's rooms, but a short time back, when this gentleman, in a most able lecture, very fairly stated its merits. But, on the principle of an old proverb, if I may venture to say so, I do not consider that Mr. Swan carried his investigations far enough. Development is a fairly complicated phenomenon. There is something besides the mere bringing out of detail or getting density; there are the gradations, or intensity scale of the negative, to be looked after, and this I consider the real secret of universally successful development.

A photograph of nature is made up of not only high lights, half tones, and shadows, but of every gradation or *nuance* between these salient divisions. However white the paper we make our prints on may be, it will always be less so than the bright high lights, and the deepest blacks of the print will be behind the dark shadows of nature. We have then to compress the scale of tones of nature into the short gamut that our printing processes give us; and it is therefore evident that the developer that can give the greatest range to this gamut will, *ceteris paribus*, be the most useful.

To make this point clearer, a certain light intensity will give the least appreciable deposit after development on the sensitive film, whilst the darkest deposit that we can admit—this point depending on the particular printing process we intend to use—we will assume to be obtained by a light one hundred times as intense. In exposing we must expose long enough for any desired detail in the shadow to impress itself on the plate. We will take this amount of light as our unit. Now any light one hundred times as bright as this unit point will then be represented on the plate by the maximum amount of deposit possible; and therefore any lights that in intensity are superior to this figure must all be represented by an equal amount of deposit; that is to say, they will all give the same appearance on the print, and we shall lose all detail in the high lights. Now suppose that, by some modification of our developer, we could so manage that our maximum deposit was only attained by a light two hundred times as intense as our standard minimum, I think it will be allowed on all hands that this is not only a valuable but an essential property.

It is to ascertain what are the capabilities of quinol in this direction, as compared with pyro-ammonia and ferrous oxalate, that I have undertaken the following experiments. I have not sought in any way to find out the developer that will give the most detail on a plate. From a very exhaustive series of experiments that I made last year, I was led to the conclusion that no alteration in the constituents of the developer in any way affected the amount of detail that was brought out, provided that sufficient time were given. I believe Mr. Cadett has also come to the same conclusion, and as my present set of experiments show the same result, I think we may consider it as an axiom, that the action of light on a dry plate is absolute, and no strengthening of the developing agent can bring out what does not really exist.

Mr. Swan, in his experiments, made a comparison by means of ordinary negatives. I have seen these negatives, but I found it most difficult to make any very reliable deductions from them, and even Mr. Swan was obliged to acknowledge that it required a long and careful examination; I therefore in my experiments decided to use a graduated sensitometer screen, which may aptly be described as a negative reduced to its simplest expression. The plates used were the Castle Brand, the same as those used by Mr. Swan; they were all exposed to a uniform light behind ground glass for equal periods of time. The time was taken from a pendulum beating half seconds, and every care was taken to ensure the negatives being equally exposed.

The developers compared were:—Pyro and ammonia; quinol and caustic soda; quinol and carbonate of soda; quinol and carbonate of potash; quinol and ammonia; ferrous oxalate. The pyro used was sulpho-pyrogallol, and the quinol was Byk's, and was made up the same as the pyro with four times its weight of sulphite of soda, acidified with sulphuric acid. The caustic soda was the fused, in sticks. The carbonate of soda was the anhydrous salt, and the carbonate of potash the ordinary one of the pharmacopœia. The ammonia was the ordinary so-called 880°, but I cannot guarantee its strength. The ferrous oxalate was made up of acidified saturated solutions of potassium oxalate and proto-sulphate of iron. The restrainer used was invariably potassium bromide.

At the risk of being prolix, I will again state exactly those points in development I was investigating. Some little time back I saw some photographs of Captain Abney's; they were of snow scenes in the Upper

Alps, and although the range of tones between the bright reflected light on the snow and the deep shadows of the fir-trees was enormous, yet they were all proportionally represented in the photograph, both as regards the details in the shadows of the trees and in the high lights of the snow. These plates were developed by pyro and ammonia, and Captain Abney was kind enough to make known the particular formula he used for these views, which will be found on page 24 of vol. ii. of the *Camera Club Journal*.

In my own mind, I set this result down as the standard of excellency that any developer must attain in order to come into universal use.

How far quinol was capable of doing this the following experiments will, I hope, show. I will not weary you by going through them *seriatim*, but rather give you my deductions.

Commencing with pyro, we find the following laws:—By decreasing the quantity of pyro, the alkali remaining constant, we get loss of detail and also loss of density in the high lights; if, however, we continue development long enough to bring out all the detail, then the density in the high lights has also increased, and the result is what I call normal. If, however, whilst keeping the pyro down, say, half a grain (all quantities are in grains per ounce of developer), and increase the ammonia up to four or six minims, we find that now we can get out all the details before the high lights gather any great density, and, therefore, we get a long, low curve. This is precisely what we require; we have brought out the detail in the shadows, and the high lights have not yet assumed any over density, although by the suitable addition of more pyro we can at any time get any amount that we may desire.

Now, as to the behaviour of quinol under such circumstances, I am sorry to have to admit that it totally fails; its action is very distinct from that of pyro. If we decrease the quinol we lose detail, just as in pyro, but if we increase the alkali, unlike the pyro developer, we get no increase in detail, or, what is the same thing, no increase in the speed with which it appears, unless we add the alkali to a most enormous and impracticable extent, and this is practically the same whatever alkali be used. Ammonia appears to promise the best results, but it has to be added to an enormous extent, and then green fog makes its appearance with as much vigour as in any pyro and ammonia-developed negative.

To recapitulate the salient differences between pyro and quinol. The attainment of a low curve of intensity practically means that the detail, or less exposed portions, must be brought out rapidly before the high lights, or more exposed portions, have had time to gather density, and this may be said to depend on the speed with which those details can be brought out. Now, when a small quantity of pyro is present, increase of alkali means increase in the speed with which the detail appears; but with quinol, on the contrary, increase of alkali, in reasonable quantity, does not mean increase in the speed of development. In order to obtain this the quinol itself must be increased, in which case the development can be made most rapid, but, unfortunately, it is attended with an equal increase in density. The experiments show this most conclusively. Potassium bromide remains constant throughout. As its action is always to increase density, and as I was striving to keep density down, it became unnecessary to take this salt into account, although I found that a little is necessary to prevent a general slight reduction of the presumably unexposed portions of the film.

I found no practical difference in results when using the fixed instead of the caustic alkalis; development was undoubtedly more slow, but the gradations were practically the same.

With ammonia I found the greatest difficulty in getting any sort of an image, unless both the ammonia and the quinol were increased to a very great extent. I find one note, that with half a grain of quinol no image showed after ten minutes, although twenty-five minims of pure ammonia were added. The whole of the results with ammonia give green fog and metallic fog in a most virulent degree, and prove, I think, pretty conclusively that quinol is just as prone to fog as pyro, when used with the same alkali.

Passing now to the negatives developed with ferrous oxalate, we see that the rate or speed of development increases with the amount of the potassium oxalate present, so that it is possible to somewhat vary the gradations of the scale; one curious note, on diluting the ordinary developer with water, increases the density of the negative very considerably, being directly antagonistic to the result of having the oxalate in great excess.

From the above series of experiments I am led to deduct that, as far as regards the getting out of detail, pyro, quinol, and ferrous oxalate are all equal. As regards density—that is, the getting of the greatest amount of deposit for a given time of exposure—quinol and ferrous oxalate have, perhaps, the advantage over pyro, but my pyro series of experiments do not obtain any specimens specially made with the idea of getting density, so that it is quite possible that pyro may hold its own even in this, in most cases, very undesirable respect.

With regard to getting a low intensity curve, pyro is a long way the best, ferrous oxalate comes next, and quinol last. I am, therefore, led to believe that for negative work quinol will never oust pyro, to which I consider it decidedly inferior. It is, of course, difficult to make any statement as to the anti-fogging tendencies of quinol, but I am inclined to believe that this is simply a question of the alkali that is used; with ammonia, even with small quantities, quinol gave me green fog as badly as any pyro developer ever did, and I therefore consider that it is not altogether

so successful in this direction as one has been led to suppose. Quinol is not as soluble as pyro, and therefore presents a certain disadvantage from the point of view of ready carriage; and, lastly, quinol is more expensive than pyro. Therefore, taking all these considerations into account, I do not think that quinol is destined to survive long as a developer for photographic negatives. As a developer for lantern plates, owing to the great beauty in the colour of deposit that can be obtained by it, it may possibly live long and prosper, but as a developer of negatives its restoration to the country of its birth will be as short as the historically famous restoration of the Stuart dynasty.

FIFTY YEARS' PHOTOGRAPHY.

We have already alluded to Poitevin, and we think we may safely say that what is known as photo-lithography was to a large extent worked out by this Frenchman, and here again the alteration brought about by light on gelatine in presence of a bichromate is made use of. In this case, after damping the gelatine and going over it with a greasy ink, it was found that where the light had acted there the ink would adhere. The inky picture thus obtained was originally transferred to the stone, and subsequent impressions could be taken in quantity from this transfer. Drawing an ink impression from the surface itself constitutes what we now know under the names of collotype, lichtdruck, heliotype, and various other cognomens. The carbon image, as you are aware, is a true relief, and a photo-mechanical method was founded on this by W. B. Woodbury. The presence of the colouring matter always present in carbon tissue prevents the light penetrating to the depth it otherwise would; but if we do away with the colouring matter or reduce it to a minimum, we get, on development, a very marked relief indeed. Woodbury obtained such a picture, and by forcing it into a lead plate by means of suitable apparatus, an intaglio or mould of the original was secured. Impressions were drawn from this by means of a special ink—viz., gelatine—holding a colouring material to resemble the tone of the silver. It was run into the mould hot, paper was laid on the top, and the whole was tightly pressed in a press of a peculiar construction. When cold, the paper had the gelatine picture attached to it, and the mould was then ready for a repetition of the process. Woodburytype, as this mode has been called, may be said to have come into existence in 1864. It was duly protected by patent. In 1880 a modification of the process was brought forward by Woodbury, where the relief itself, protected by a layer of tinfoil, was employed to draw the prints from. It received the name of Stannotype. Many other photo-mechanical processes were devised by Woodbury, who has been—appropriately, I think—styled the *Carton* of photography. The title is certainly well-deserved, when we see first-rate likenesses of celebrated men and women retailed in the shops for the modest sum of one penny. Woodbury died in somewhat straitened circumstances on September 5, 1885.

We have already referred to Poitevin, who may be reckoned the Woodbury of France; but we wish at this point to refer to a process worked out by Poitevin, and one which can be made to give good results. Organic matter in the presence of a bichromate again forms the starting-point; but another property which light induces, founded on the hygroscopic nature of the substance employed, dextrine and sugar for the most part, is made use of. After exposure a fine impalpable powder is dusted over the plate, and it adheres in those parts protected from the light; hence, a negative gives a negative reproduction reversed as regards right and left. From the nature of the operation involved, the name of the "powder process" has been given to it. The salts of iron have been found to give similar results to the bichromate usually employed. Photographic research does not seem to be one of those things which tend to benefit financially the men working at it. Like Woodbury, the Frenchman whose process we have been considering died unrewarded. He seems to have all his life worked at photographic reactions and photographic applications, and I know of no more suggestive book than Poitevin's *Traité des Impressions Photographiques*. Louis Alphonse Poitevin was born at Conflans in 1819, and died in his natal town on March 1, 1882. We cannot go further with his career, but France, mindful of its distinguished men, has erected a commemorative bust to Poitevin in the town of Conflans.

We will simply refer to one other photographic process, and one, perhaps, which has been made to suffer through being protected by patent, although this no longer applies, for all are now free to use it—I refer to the platinotype process. The merit of discovery of this mode of printing is due to an Englishman, Mr. W. Willis, jun., who took his first patent out in 1873, although subsequent patents followed in 1878 and 1886. The nature of the chemical reaction involved is, however, one of those discovered as far back as the days of Herschel, and is due to the action of light on a ferric salt, reducing it to the lower state of oxidation. The ferric salt is mixed in the first instance with a salt of platinum, and paper coated with this mixture, after exposure, say behind a negative, is floated or drawn over a hot solution of potassium oxalate. When the light has reduced the ferric salt to the ferrous state, then metallic platinum is deposited. We may simply add that a direct printing on platinum process has lately been devised, but it would appear that the printing is a very tedious affair.

• Concluded from page 232.

We have not time to go into all the various salts which from time to time have been brought forward, and on which light has been found to have a decided influence. Salts of uranium have been largely experimented with, and their behaviour seems to be very much the same in character as that of iron. The salts other than iron, the chromates and those of silver, affected by light, would require a paper to themselves. I feel I have trespassed sufficiently on your patience as it is, but perhaps you may allow me to conclude with a quotation I have, on a previous occasion, given, and one which shows how photography was regarded by one who knew nothing of the practical working of it, but who looked only at its influence. I refer to what Jane Welch Carlyle wrote:—

"Blessed be the inventor of photography! I set him above even the inventor of chloroform. It has given more positive pleasure to poor suffering humanity than anything that has cast up in my time, or like to: this art, by which even the poor can possess themselves of tolerable likenesses of their absent dear ones. Mustn't it be acting favourably on the morality of the country? I assure you I have often gone into my own room in the devil's own humour, ready to swear at things in general and some things in particular, and my eyes resting by chance on one of my photographs of long-ago places and people, a crowd of gentle thoughts has rushed into my heart, driven the devil out as clean as ever so much holy water and priestly exorcism could have done. I have a photograph of Haddington Church tower and my father's tombstone in it, of every place I ever lived at as a home, photographs of old lovers, old friends, old servants, old dogs."

W. Lano, JUN.

ON THE BINDING OR FRAMING OF LANTERN SLIDES.

[A Communication to the Edinburgh Photographic Society.]

In my early paper on *Stands for Viewing Transparencies on Glass* I advocated very strongly the merits of these, and would refer you to what is there said. That was twenty-six years ago. Lantern slides have since then, no doubt, gone on growing in favour, but not so rapidly as might reasonably have been expected. However, I quite recently heard that American visitors to our city were showing a decided preference for these to even the beautiful paper photographs now so easily procured, as the form in which to carry away *souvenirs* of their visit to Scotland; and I fancy the preference for the diaphanous photographs would become very much more decided and widely extended if instruments for viewing them satisfactorily without the lantern were readily procurable at moderate prices.

But though much may be claimed for the permanence of the pictures on the slides, what can be said for the durability of the paper bindings? Used even carefully I find they soon get into a frayed and loosened condition. Then what a troublesome business it is to gum on the four strips of easily torn paper; and these do not suffice, for, to give a satisfactory outline to the picture, it is necessary to insert a paper mask between the two glasses.

In *THE BRITISH JOURNAL OF PHOTOGRAPHY* for January 3, 1868, in a paper signed "Bivalve," I suggested the use of one piece of paper cut to a proper

shape, as there figured, to do in a firmer way all that the mask and four strips of paper performed.

Eighteen years later the same idea had occurred to Mr. Thomas Gulliver, as he describes and figures exactly such a mount in *THE BRITISH JOURNAL OF PHOTOGRAPHIC ALMANAC* for 1886, at page 150.

I show on the table the different stages of the system of mounting I now follow. It will be observed that both faces of the slide are now similarly masked. The form of paper to effect this for the commonest shape of opening is shown by Fig. 4; this, after the face has been well pasted, is placed on a loose piece of thick flannel; the transparency, with covering glass tacked on with thin layers of sealing wax inside the corners, is then imposed face downwards upon the mount and brought to coincide with the square A B C D. The sides marked W and E are then turned over upon it by lifting the edges of the flannel one after the other, and the operation finished by next turning over sides N and S.

Now, what are the caterers of photographic materials about that they do not provide these things? Why should I have to cut out each separate mount with gun-wad punch and scissors when one hundred could be stamped out at one operation, and in a few seconds, by means of a pair of proper steel cutters, after the fashion of envelope blanks?*

It is desirable that these paper mounts should be cut from a smooth, thin-nish, tough paper; in fact, a pure linen rag paper, if such can now be got; that there should be supplied varieties giving choice of differently shaped openings; and that they should be of some nice light colour, to allow of writing on them the titles and particulars in ordinary ink, for I believe the advantage of making the framings black is illusory. It will be observed that the blanks I use are such that at the corners the paper crosses well over upon itself, thus securing firmness of hold and also a mitre-like joint.

I confess that it is sometimes impossible to make with these single-piece mounts a very neat job at once. This arises from the glasses varying much in thickness, and often departing considerably from the exact sizes of $3\frac{1}{2} \times 3\frac{1}{2}$, but a little after-trimming with a knife will seldom fail to give a satisfactory finish.

R. H. Bow, C.E., F.R.S.E.

LORD RAYLEIGH ON EXPERIMENTAL OPTICS.

VI.

LORD RAYLEIGH, in the course of his sixth lecture at the Royal Institution on the above subject, said that some waves of a beam of light neutralise other waves, somewhat as in the case of waves of sound, as demonstrated in his preceding lecture, but that if a convex lens be placed in the path of the beam of light, the properties of the lens are such that it brings to a focus all the waves, including those which otherwise would have been neutralised. Although the waves passing near the edge of the lens have farther to travel than those passing through the centre, the central waves have to pass through a greater thickness of glass, and as light travels more slowly through glass than through air, the central rays are more retarded, so that all the rays passing through the lens reach the focus at the same time. The waves not previously in accord are brought into accord at the focus. In the case of a prism, the parts of the wave front which pass through the thick end are retarded more than those which pass through the thin end.

He then dealt with diffraction phenomena, saying that the first gratings were made by Fraunhofer, who fastened gold leaf to glass, then scratched it into fine lines by means of a machine. Later on it was found that diamond scratches on glass would make a more permanent grating, and later still it has become common to rule lines upon speculum metal, because glass, being of unequal hardness, perhaps from the presence of uncombined particles of silica, is found to injure the diamond points, and good diamond points for the purpose are difficult to obtain. From 3000 to 15,000 or 20,000 to the inch are about the range of lines in gratings, and speculum metal being softer than glass, is less trying to the diamond point. Gratings do not behave precisely alike, because of peculiarities in the ruling. He here projected upon the screen an image of the carbon poles of the electric lamp, and by the use of a grating showed how the latter projected a central image of the points, and on either side thereof a succession of spectra, with spaces between some of them; the spectra most distant from the central image overlapped each other. Next he repeated the experiment, but substituted an image of the slit of the electric lamp for the carbons; more perfect but less brilliant central image and spectra were the result. A diffraction spectrum has about one-tenth the brilliancy of the ordinary spectrum; the central image gets the lion's share of the light, the rest of which is divided among the total number of spectra produced. The blue end of a diffraction spectrum is always nearest to the central image. Although a diffraction spectrum is lower than the ordinary spectrum in brightness, it resolves fine lines better, and affords a direct and the most accurate method of measuring wave lengths. The prismatic spectrum varies to a certain extent with the angle of the prism, and the substance of which it is made; it is a spectrum depending upon the properties of the material used; it also dilates the violet end of the spectrum; the diffraction spectrum is more properly treated as the standard.

In diagrams of the distribution of the energy of the prismatic spectrum, a great hump in the invisible region beyond the red end denotes the position of maximum heating effect; this hump is due to a peculiarity of the prism, and is much lowered when a diffraction spectrum is used; altogether the diffraction spectrum is the best to use in stating scientific results. A difficulty about the prism comes in in experiments with the invisible heat rays; you must first make sure that it is transparent to

* Were this done the mounts could either be supplied without any opening, which could afterwards be cut of any size or form desired, or, provided the shape given by the folding-over margins was a square of sufficient area to ensure that its outline would not trench in any way on the other opening, a choice might be afforded of square, circular, oval, oblong, or dome-shaped apertures of various dimensions.

them, or must ascertain its degree of transparency. Professor Langley has discovered that glass with no green tinge is much more transparent to the red and the ultra-red rays than other kinds of glass, and in the more refined experiments with ultra-red rays glass must be abandoned and rock-salt substituted as discovered by Melloni.

Lord Rayleigh said that he did not think the scale of wave-length the best to be used in research with the spectrum, and that he believed Mr. Johnstone Stoney was the first who raised the question whether the velocity of vibration should not be used as the scale. On theoretical grounds the scale of frequency of vibration is best to employ, but that of wave-length is the most convenient.

A SECOND NOTE REGARDING STANDS, BY MEANS OF WHICH LANTERN SLIDES MAY BE SATISFACTORILY SEEN.

[A Communication to the Edinburgh Photographic Society.]

As indicating the diaphanous character of the lantern slides, &c., I would suggest that the instrument for viewing them should be called a diaphanoscope, or this shortened into diaphascope.

The "Diaphascope," a Menoclar Form of Stereoscope. (Seen in profile.)

In the earlier form of the stand, which I described before this Society twenty-six years ago,* I gave the preference to ground glass as an illuminating background for the transparency, but placed several inches further away, so that the appearance of grain would be lost by being thrown much out of focus. And for the denser transparencies, at least, I still think this background the best, as giving a stronger illumination.

Shortly afterwards I had several instruments made, with paper substituted for the glass, not as being better, but from allowing a more portable form to be adopted. This is shown by the figure. The slide is at S; on B is laid the cardboard to form the background; the lens, L, is fitted to a draw-tube, which can be adjusted to suit different sights, being pushed further down for near-sighted persons. B has a dovetailed connexion with A, and A with C, so that the whole can be easily taken to pieces and packed in small compass.

Two constructive details of the instrument in either form are, first, to provide a lens capable of giving a comparatively flat field over the extent of a lantern slide, and that with a considerable magnifying power; and, second, to enclose the transparency, so as to get rid of the bad effects of light being reflected from its face.

As to the lens, I have usually adopted a simple plano-convex one of about three and a quarter inches focal length, and one and a quarter inches or more in

Diagram illustrative of the Optical Principles involved in the Construction of the Diaphascope.

diameter. This gives a fairly good result, and the picture is seen in the instrument much more perfectly, I think, than it ever is on the wall screen. I

* THE BRITISH JOURNAL OF PHOTOGRAPHY for March 2, 1863, page 101.

may here offer a few remarks upon the conditions under which a plano-convex lens acts. First, let us proceed as if to take a photographic view with such a lens. The best position for the stop (see figure) for the margined pencil of rays, S A, will be at S, arrived at thus:—C is the centre of curvature of the face A D, and A S is taken = $AC + \mu$. Now the pencil of rays S A will pass into and out of the lens in the radial direction C A B, and will consequently have the longest possible focal distance A B. And for intermediate pencils this is nearly correct. The curvature of the field will have C for its centre, and therefore a radius of curvature equal to the focal length, augmented by the radius of curvature of the convex face of the lens.

On the table I place a transparency printed from a negative taken by such a lens.* It is better than might be expected, especially when we consider that little advantage can be got from using a very small stop. A very small stop would reduce the aberrations at the middle region of the picture, but would have very little ameliorating effect upon the chromatic confusion at the margins. The stop used in this instance was equal to one-twentieth of the focal length. Radius of convex face = 1.75, focal length = 3.3, radius of curvature of the field fully five inches; angle of view embraced by three-inch width of negative = 52°.

In a paper I read before this Society on May 6, 1883,† I described my plan of mapping down the curvatures of the field, and insisted that it was quite as important to keep the curves given by the primary and secondary foci from separating very far as it was to approach to an average flatness of field. Now I attribute much of the comparatively good effects got by this simple lens to the fact that with it the primary and secondary foci are united, and consequently there is no astigmatism.

Let us now consider the action of the lens when employed to view the photograph. Suppose that an eye is substituted for the stop in the figure, the centre of the eyeball should coincide with the point S; and let us now regard the pencils of rays as travelling back again from the picture. Thus the rays of the divergent pencil from point B are rendered parallel by the lens at A, and entering the eye at the same angle they had when in the first operation they were received from the landscape, they next become focussed on the retina. As the eyeball oscillates in its socket it receives in succession the other pencils, and thus the picture is viewed in perfect perspective, the distortions (as E G) being corrected by the reverse action of the lens on the same principle as I explained in a paper read before you on October 21, 1883.‡

I prefer using a high magnifying power in the diaphoscope, even when this runs counter to the theoretical rule, which prescribes the adoption of a lens of the same focal length as was used in taking the negative in the case of equal or contact printing; or if the transparency be a reduced copy from a large negative then a focal length reduced in the same ratio. Two advantages are gained by using the powerful lens—we see the minutest details more perfectly; and from the larger apparent angle of view the picture gives a feeling of expanse.

I have placed on the table two diaphoscopes with lenses equal to 3.3 and five inches respectively. In these are shown identical transparencies, and I think any one on examining these, one after the other, will be struck with the contracted character of the view as seen by the five-inch lens. The apparent angles of view will be about 52° and 34° respectively; the actual view as taken on the negative was, I believe, 37°.

In taking negatives specially for the purpose of printing lantern slides by contact, it would generally be advisable, for several reasons, to use a view lens of short focal length, and so do away with any objection on the score of false perspective.

And although the non-achromatic lens as applied to the diaphoscope behaves fairly well, it would no doubt be better to use an achromatic one, and the cost of such, if made in numbers, should not be great. The focal length I should prefer would not much exceed three inches; and there is this to be said in favour of the plano-convex, or moderately meniscus achromatic, that the eye may be placed very near to it, and consequently the diameter might be reduced to an inch or less.

Before concluding, I would call attention to the differently coloured papers or carbonisers that may be used as backgrounds. For ordinary pictures the best effect is, I fancy, got by using a warm stone colour, or orange. For wintry or moonlight scenes a good effect is produced by the pale lilac, and for sunset effects use the crimson or red.

R. H. BOW, C.E., F.R.S.E.

THE CAMERA IN SWITZERLAND AND ON THE ALPS.

[A Communication to the Dorned Amateur Photographic Association.]

SWITZERLAND, "the playground of Europe," as it has been happily called, is so easily reached, and its attractions are confined within such narrow limits, that it has become to many Englishmen more familiar than the holiday resorts of their native land; and it is certainly more easy within a limited time to carry away with one a good general idea of its beauties than of some other European countries. The picturesque nature of its scenery, which gives it interest in the eyes of the general traveller, makes it a happy hunting ground to the photographer, and yet, though books innumerable may be found which describe Switzerland and its scenery for the traveller and tourist, there are none, so far as I know, written for the amateur photographer, giving him hints as to light, exposures, points of view to be chosen, and points of view to be avoided. And it is too trying to the patience and temper of the enthusiastic amateur to have to waste precious sunshine in hunting for picturesque spots which when found are useless for photography. Have any of you gentlemen ever been told of a splendid view to be obtained from a certain hill, and, after a hot walk up a steep hill for a couple of hours heavily laden with your photographic impedimenta, you have reached the spot and found a fine panorama stretched out before you but quite useless except to the man who is provided with a 24x18 camera or a lens like a telescope? What would the panorama from the Rigi or Mont Blanc look like on a quarter-plate? There might be plenty of magnificence in the panorama, but there would be little of it on the quarter-

plate. "Oh," said a friend, "I always look at the photographs in the shop windows, and find out through them what there is to take." It is always useful to examine the photographs in the shop windows, and there is always something to be learnt from them, if it is only what to avoid, for it is not every good manipulator who has the eye of an artist.

It would be a convenience to photographers if a kind of photographic Swiss *Baedeker* were compiled, giving particulars of the principal views in the locality—how they can be reached, the best hour of the day for photographing them, the lenses, with length of focus best adapted for taking them—with a note of the most picturesque spots within a reasonable distance, to which should be added a list of hotels in which dark rooms are provided. I have not the presumption to suppose that these conditions will be perfectly fulfilled for the places named in the short lecture I have the honour of delivering before you, even so far as it goes, but I hope the remarks I may have to make and the lantern pictures by which they will be illustrated may be useful to any one who contemplates photography in Switzerland and has had no previous experience in the country.

I took six dozen plates with me, and lost only six—two through over exposure, four by double exposure; there were three duplicates which I have not printed, and I brought back six plates; the other fifty-seven pictures will be exhibited on the screen.

As to outfit, portage is cheap in Switzerland; it is, therefore, more easy to use a large camera than in some other countries; but I prefer to employ porters when I please, and to be independent of them when it suits my purpose. With a big camera you are tied to a porter; you can move nowhere without him. I should, therefore, even in Switzerland, prefer a camera I could carry myself rather than be entirely dependent on others; and I have no cause to regret having taken a half-plate camera, especially as the enlargement of pictures is so readily effected.

This half-plate camera had four double backs, the whole packed comfortably into a waterproof canvas case, leather bound, to the top of which the legs were strapped; the whole was carried by means of a broad woollen web (not leather strap), which was passed down the sides of the case and underneath the bottom, giving good support, and loose enough at the top to sling over the head and one shoulder. As regards lenses, I took but one, a Dallmeyer rapid rectilinear; had I taken another lens I should have preferred a long-focus to a short-focus lens; the latter might have been useful in some of the towns, though I managed well enough without it, the former would certainly have been very useful on the mountains. As I stated before, I took six dozen plates. I tried films, but in my hands their action was not sufficiently certain to induce me to depend upon them. The rest of the outfit consisted of a folding lamp, two trays, a light-tight plate box, a small wide-mouth bottle containing pyro sufficient for the plates in twenty-four-grain packets (the pyro compressed took up very little space), a bottle of ammonia and brouide, and a bottle of bromide in solution for over-exposed plates.

I anticipated some difficulty at the Custom houses, as the Swiss have lately put a duty upon imported plates. I found none anywhere; the officials were everywhere most considerate and courteous. I was asked on the Swiss frontier what number of plates I had and the size, the officials accepted my statement, and charged a small duty, and allowed the baggage to pass without examination.

The only addition to the outfit I could suggest would be to include a second front carrying two lenses, with a loose partition for the half-plate camera, so as to make it available for views either of half-plate or stereoscopic size. Undoubtedly photographs of Swiss scenery can be best enjoyed in the form of stereographs; only in that form can distance be represented and a natural relief obtained. Some pictures I have of glaciers two miles distant and mere look, in the single picture, close at hand, and therefore insignificant; in the stereograph they would have appeared in their right proportions.

One very important point to be observed on photographic expeditions generally is to develop test plates from time to time to correct the exposures; had I omitted to do this I should have had very few pictures to show you, for it was very evident that I was over exposing on the other side of the Channel with exposures which would have done very well on this side. I found out my fault on developing one or two plates early enough to correct it before reaching Switzerland. In some few of the hotels dark rooms are provided, but as a rule the amateur who wishes to develop must either do so in his private room at night or obtain permission from, and make fair compensation for disturbance to, some local photographer to develop in his dark room at an hour when he will not be using it. Pursuing the latter course led to my introduction to some professional men of standing and repute in their own neighbourhood, and excellent fellows I found them; and through them I obtained some insight into the practice of the Continental studios. Everywhere oxalate development appears to be the method employed. On informing one gentleman that I used pyro he smiled and evidently thought I was to be pitied; they had given up pyro long ago, he said. On seeing the negatives produced by pyro, however, his opinion underwent a change. One, *Hagmaling in the Alps*, he was pleased to style "magnifique." He particularly remarked the extreme delicacy and sharpness of the image, the latter due partly to a favourite Dallmeyer rapid rectilinear, but, undoubtedly, in no inconsiderable degree due to the ammonia developer; for on comparing with his oxalate negatives I found some of the finer detail obliterated, if I may so express it, by the piling up of the lights, which seems necessary in using an oxalate developer if great contrast and pluck are required, for the deposit being of a blue-black colour it is much less actinic than the yellow brown of the ammonia and pyro. His negatives had the qualities and very much the appearance of good negatives of the old collodion type.

A dark room is, of course, not a necessity for the changing of plates; my cardboard folding lantern, with its window of ruby material, a candle end inside, and a bit of tin plate on the top, gave a safe and sufficient light for changing plates at night.

If the route to Paris is taken via Chalais and Dorn, Amiens will be passed. A night can be profitably spent there. The Cathedral is well worth a few plates. Good views of the exterior can be obtained: of the south-east, from the street running south from the east end; of the south porch; of the west end, from the south-west; and of the great west doors. The first three can be taken in the morning, the two last named at two in the afternoon; the sun will be round sufficiently by that time to throw up in good relief the carved work, and there will be sufficient time to take the fast train for Paris. The exposure in June with Hford ordinary or Miall's plates will be one second or less, with f/34. There are some interesting old figure subjects carved in high relief which are well worth a plate or two; they will be found inside the church, on the walls of the choir, but outside of it.

There are interesting views to be obtained in Paris, but the difficulty is to know from whom permission can be obtained to photograph them; half a dozen different officials may have to be interviewed for permission to take as many pictures. To take

* On the Management of Non-achromatic Lenses. See my remarks in THE BRITISH JOURNAL OF PHOTOGRAPHY, 1886, page 221.

them without leave is to court trouble. If the views are worth it, three or four days at least should be allowed for photographing them. There may soon be greater facilities for photographing in Paris if the members of the new amateur photographic society lately formed there act in a fraternal manner towards their *confrères* in the art.

Not many people stop at Pontarlier on their way to Switzerland, *à la* Dijon, yet the neighbourhood is interesting, in the midst, as it is, of the fine scenery of the Jura mountains. In the town itself there is nothing particularly striking; the old gateway might be worth a plate, and a view may be obtained from the public gardens and one of the bridges, but there are good views of forest scenery with a mountain stream a mile or two out of the town, and of mountain scenery at greater distances. We happened during our stay there to come in for the *Fête Dieu*, a spectacle which, in its setting of a little old-fashioned French town, was worthy of any painter's brush. Some of the groups were most interesting and picturesque. Unfortunately the sky was exceedingly dull and overcast, and shutter work was entirely out of the question. The photograph before you of the funeral party headed by the priest and acolytes, &c., was taken on the following day; the light was better, but still very poor. The picture, however, such as it is, was secured by a drop shutter and lens stopped down to *f*-11.

On the way from Pontarlier to Neuchâtel, the train winds in and out, first round one spur of the Jura mountains, then round another, giving in great variety some exquisite views; not many, so far as I could judge, would lead themselves to photography from the spots from which we viewed them; there was, however, one exception—a little valley bounded by mountains with a brawling stream running down it, near, I think, the third station before reaching Neuchâtel. I intended to go back for it, but the trains ran inconveniently and I could not spare the time. The first view taken in Neuchâtel was the photograph of the market-place, which was taken in the early morning with the *f*-11 drop shutter Ilford extra rapid; it would have been much improved if the people had been in national costume, but here, as well as in Italy and elsewhere (Dorset included), the national costumes are fast disappearing. The building with the towers in the background is of great antiquity and is worth a plate to itself. Whilst waiting for the people to move on from the front of the lens, a pretty-looking Swiss girl came up and modestly asked, "Does Monsieur take portraits, and how much would he charge for taking hers?" Monsieur inwardly thought he would be only too pleased to take half a dozen for nothing if only Mademoiselle had been in costume, but what he said was hypocritical: "Monsieur regretted that he was only a landscape photographer, and he feared that no photograph of his would do justice to Mademoiselle." Mademoiselle retired looking pleased, though with a shade of disappointment.

The chief interest of the place centres in the Schloss, the palace in ancient days of the kings of Neuchâtel, now converted into Government offices; built on an eminence it dominates the town, and is a prominent object when seen from any part of it. The best view of this fine group of buildings is obtained from the railroad, a few yards from the pointsman's cottage. Ask the way. You will have to mount an innumerable number of steps, but the view a few yards along the line from the cottage will well repay you—the chateau towering up high above the town, and in the background the lake with the plain beyond ending in the range of the snow-capped Alps. The view should be taken either in the early morning or in the evening; by day the mountains are capped or totally obscured by mist; the exposure will be very short, one or one and a half seconds, with plate of ordinary rapidity, stop *f*-32, time half-past six in the morning, June 12. You will have to descend and remount to reach the Schloss; two views at least are worth taking there, the entrance and *façade* of the palace, and the cloisters of the chapel. The former should be taken between half past eleven and twelve, exposure one and a quarter seconds in June, *f*-33, the latter three seconds, same stop. The chapel is not worth a plate, it has been so mutilated; but there is a curious monumental group inside of the twelfth century, consisting of fifteen life-sized figures.

(To be continued.)

W. MILES BARNES.

INTERNATIONAL PHOTOGRAPHIC EXHIBITION, CRYSTAL PALACE, S.E. LANTERN DIVISION. LIST OF AWARDS. Section A. Amateurs only.—*Class I. British Landscape*, Seymour Conway; *Class II. Foreign Subjects*, W. A. Greene; *Class III. Seascapes*, A. R. Dresser; *Class IV. Architecture—Exterior*, J. B. Hilditch; *Class V. Architecture—Interior*, T. M. Brownigg; *Class VI. Animals*, Lewis Medland; *Class VII. Figures in Motion*, Henry Little; *Class VIII. Microscopical*, F. H. Evans; *Class IX. no award*; also medal to F. Brighlman for his exhibit in *Class III.* Section B. Open to all (forty-eight slides).—*Class I. British Subjects*, G. W. Wilson & Co.; *Class II. Foreign Subjects*, Cyril Frith; *Class III. Slides produced by Mechanical Processes*, The Sciopticon Company.

AMERICAN EXHIBITION. AWARDS.—The Board of Judges appointed to make the awards of diplomas for work at the Joint Exhibition of the Society of Amateur Photographers of New York, the Photographic Society of Philadelphia, and the Boston Camera Club, fully make the following awards:—*Diplomas for Special Excellence*.—1. For landscape or marine views.—Harry Tolley, Nottingham, England, No. 524, *On the Lonely Shore*. 2. For portraits.—Frederick Gutekunst, Philadelphia, No. 303, *Miscellaneous Portraits*. 3. For genre subjects and figure compositions.—W. W. Winter, Derby, England, No. 608, *My Mammy*. 4. For work by ladies.—Mrs. S. M. Cleveland, Philadelphia, No. 311, *Entire Exhibit*. 5. For Enlargements.—William H. Rau, Philadelphia, Nos. 340 to 343. 6. For Lantern Slides.—Professor Henry A. Rowland, Baltimore, Md. 7. For applied photography, scientific or technical.—Prof. Henry A. Rowland, Baltimore, for photographic maps of the normal solar spectrum, second series, 1888. *Diplomas for Excellence*.—For entire exhibits.—Frank M. Sutcliffe, Whitby, England; William Parry, Shields, England; J. P. Gibson, Hexham, England; John Bartlett, Philadelphia;

Charles L. Mitchell, M.D., Philadelphia; George B. Wood, Philadelphia; Paul Lange, Liverpool, England; Robert S. Redfield, Philadelphia; Richard Keene, Derby, England; Harry Symonds, Portsmouth, England; S. W. Burnham, Lick Observatory, California; The Rev. F. C. Lambert, M.A., Cambridge, England; H. A. Latimer, Boston, Mass.; A. K. F. Trask, Philadelphia; George A. Nelson, Lowell, Mass.; R. T. Hazzard, Philadelphia; Clarence B. Moore, Philadelphia; Mr. and Mrs. W. J. Anckorn, Arbroath, Scotland.

Our Editorial Table.

FLASH LIGHT FAMILY GROUPS.

WE have before us a series of domestic groups taken by Mr. Wm. Taverner, jun., by means of Hart's patent magnesium flash lamp. We learn that two of these lamps were used in the production of each of these home scenes, which may account for their delicate softness combined with vigour, while free from heavy or harsh shadows. The grouping and general arrangements are not less artistically made than skillfully carried into photographic effect. They show the possibility of taking groups of a high order of excellence with a total independence of daylight. For these pictures Mr. Taverner was awarded, and most justly so, a medal at the recent Crystal Palace Exhibition.

AN IMPROVED FLASH LAMP.

By F. W. HART, Kingsland Green.

SINCE the time when Mr. Hart first exhibited at the North London Photographic Society the outcome of his experiments, made with a view to the further improving of the Hart & Bishop lamp, he has been assiduously at work in effecting still greater improvements than those first foreshadowed, until at last it is questionable whether any further room is left for improvement. The lamp, as placed in our hands, is of what we might designate the domestic order, in the sense that it is suitable for interior views, or small groups in the parlour or drawing room, in contradistinction to the powerful battery required for embracing the stage of a theatre, the dining tables of a restaurant, or a piece of architecture on the opposite side of a street—feats which we have placed on record as having been successfully effected. This "domestic" article consists of two lamps, capable of being separated from each other to any reasonable distance, to suit the exigencies of the lighting required. They are by rubber tubes connected with a metallic reservoir, in which is kept a store of compressed air, and which is thus charged when wanted by the action of the hand upon a pneumatic ball. The lamp itself differs in no essential respect as regards its burning qualities from that which we described in these pages over a year ago. Each having been charged with the few grains of magnesium powder required, the spirit lamps having been lighted, and everything in readiness for the exposure, the operator releases a tap at the reservoir, and simultaneously both lamps emit a dazzling sheet of flame.

It is very evident from the construction of the apparatus that simultaneity of flash would occur if there were twenty lamps instead of two. There are numerous ingenious appliances in the shape of valves, &c., connected with this elegant outfit, all of which have been protected by patent, particulars of which will subsequently be described in our columns devoted to patent specifications when their publication will have been matured.

IMPROVED BATH WITH CIRCULAR FLOW OF WATER FOR WASHING PHOTOGRAPHIC PICTURES.

No. 838. WILLIAM ROOKE, 290, Caledonian-road, Middlesex.—January 16, 1889.

THE object of this invention is a novel construction of bath in which photographic pictures can be washed by a travelling or moving flow of water, said apparatus having a siphonic draw-off.

For the purpose of my invention I construct a circular pan or trough and supply water at an angle at the top for a circular flow.

The side of the pan has a well in which is a turned-up end of a pipe, this being in connexion with a syphon. The bottom of the syphon pipe is in connexion with perforated screens provided at the lower periphery, so that the draw-off by the syphon is in excess of the inflow.

The short pipe in the well is for breaking the inflow when the water has reached the level, the pan then filling up again for a fresh syphoning.

The claims are:—1. The construction and arrangement of a bath for washing photographic pictures, in which bath an automatic siphonage is established for partially emptying said bath and for automatically breaking the siphonic action for a refilling of the bath as described and substantially as shown by the annexed drawings. 2. The improved bath shown on the annexed drawings, in which a circular or equivalent swilling or moving body of water can be maintained for washing photographic pictures, said bath being furnished with means for automatic siphonage for partially emptying and means for automatically breaking the siphonage for the refilling, all as set forth.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
April 29	Bolton Club	The Studio, Chancery-lane, Bolton.
May 1	Coventry and Midland	The Dispensary, Coventry.
" 1	Edinburgh Photo. Society	Professional Hall, 3, George-street.
" 1	Photographic Club	Anderson's Hotel, Fleet-street, E.C.
" 2	Bolton Photographic Society	The Baths, Bridgman-street.
" 2	Leeds	Philosophical Hall, Leeds.
" 2	Dundee and East of Scotland	Lamb's Hotel, Dundee.
" 2	Glasgow Photo. Association	Religious Institn., 177, Buchanan-st.
" 2	London and Provincial	Masons Hall Tavern, Basinghall-st.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

APRIL 23.—Mr. William Holford in the chair.

Mr. C. WOLLASTON exhibited a piece of apparatus he had made for testing the speed of shutters working between the lenses, showing their speed at different portions of their path. It consisted of a short piece of tube which he substituted for the lens; the front of the tube was closed by a disc across which a few holes were bored in a straight line; the back of the tube was similarly closed, but the disc there pierced with a row of pinholes about one-tenth of an inch apart; close behind this arrangement was a disc, which, by multiplying gear, could be made to rotate accurately at a speed of five thousand seven hundred and sixty degrees per second, and was covered with a sheet of sensitive paper. This arrangement was exposed to sunlight, and on releasing the detent of his shutter, concentric curved lines were produced upon the disc, and appeared after development; they showed the time occupied while the shutter was giving an aperture of $f/32$, $f/16$, $f/8$, and so on. The greatest speed he had registered was one three-hundred-and-fiftieth part of a second. During the time of opening and closing of go-and-return shutters the most useful part of the lens is not in action for nearly half the period, and they necessarily do not give such good definition. He had recently applied Newman's brake to his shutter.

The CHAIRMAN remarked that with the temporarily small apertures of those shutters which first open at the centre of the lens the picture is sharpened all over.

Mr. FRIESE GREENE complained of the weight of Mr. Wollaston's shutter.

Mr. WOLLASTON replied that he could not cure that.

Mr. T. BOLAS remarked that it would be of scientific interest if Mr. Wollaston would obtain a diagram showing the speed at different portions of its path of a drop shutter while being drawn down by a piece of elastic.

Mr. FRIESE GREENE exposed a bromide plate, cut it in two, and placed one-half of it face upwards on a piece of zinc larger than the plate and covered with water containing a trace of sulphuric acid. A current from one large cell of a bichromate battery was passed through the zinc. After two minutes or so of this treatment it was taken out and placed with the other half of the plate in a quinol developing solution. An image came out on the latter half, but none on the half which had been over the zinc. The latter half was then again exposed and afterwards placed direct in the developer, when the last image impressed came out. Although, he said, one would suppose all the current to have gone through the zinc, yet by induction, or otherwise, some of it seemed to have acted on the film and "extracted" the latent image. He had found that platinum would do as well as zinc, but in all cases the metallic surface must be large.

Mr. A. COWAN would like to see the experiment repeated without the zinc or the battery.

Mr. GREENE had no more solutions, but he had tried what Mr. Cowan suggested and had not obtained the result.

Mr. BOLAS said that he and Mr. Arnold Spiller thought it likely that some electrolytic decomposition of the acid, despite the zinc conductor, released some oxidising agent at one of the electrodes and thus produced the result.

Mr. SEBASTIAN DAVIS said that it was understood that if a film were oxidised in any way the latent image thereon was destroyed; he remembered that

Captain Abney had used peroxide of hydrogen for the purpose. In reply to a question, he said that he still preferred development by putting plates in the alkaline solution first, and then adding quinol as required to bring out the desired class of image.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

APRIL 18.—Mr. F. P. Cambrano in the chair.

Mr. J. H. Fulton was elected a member of the Association.

Mr. J. R. B. WELLINGTON read the rules drawn up by a sub-committee for a competition among the members for the production of the best contact prints on paper from three selected negatives; the competitors were to be allowed to introduce clouds from their own cloud negatives if they so desired, and to use what process they liked.

"Competition (No. 2) for Prints on Paper.—The undernoted rules to be adopted by competing members:—1. The three varnished negatives selected by the sub-committee to be the only ones used in competition, with the exception that competitors may use their own cloud negatives or portions of any other negatives. 2. All the competing prints are to be by contact. 3. Each competitor to be entitled to retain the negatives for printing purposes for a period not exceeding fourteen days, when they are to be handed over to the next competitor in rotation on the undernoted list. The last on the list to hand the negatives to the Hon. Secretary. 4. Each competitor before parting with the negatives to remove any markings, retouching, or other such marks which he may have made upon them. 5. A *nom-de-plume* to be placed by each competitor on his exhibits, and a sealed envelope containing his name to accompany them, with the *nom-de-plume* written on the outside. 6. Competitors are at liberty to print from each negative in one or more processes. The Hon. Secretary will give due notice when the exhibits are to be sent in to him. They will be voted upon by the members present at a weekly meeting of the Association, date to be duly announced by the Hon. Secretary."

Among those who will compete are Messrs. Cooke, Wellington, Cambrano, Brignshaw, and Cox.

The rest of the evening was passed in the exhibition of lantern pictures by means of the optical lantern. Mr. F. A. Bridge exhibited some interesting views of Bruges and Ghent, and Mr. J. J. Brignshaw some views of Treport and Antwerp, also some lantern slides of microscopic subjects. Views of home scenery were exhibited by Messrs. Wellington, Hastings, Cox, Pask, and Atkins.

NORTH LONDON PHOTOGRAPHIC SOCIETY.

APRIL 16.—Mr. J. Traill Taylor (President) in the chair.

Mr. W. T. CORENTON passed round some bromide prints developed with both hydroquinone and ferrous oxalate; the whites of the former being discoloured.

Rev. E. HEALY advised an acid bath to remove the yellowness.

Mr. J. OAKLEY thought that hydroquinone gave much better negatives from over-exposed plates than pyro; he also considered it gave better results on bromide paper than ferrous oxalate.

Mr. F. G. READER had found it stain bromide paper.

Mr. L. MEDLAND showed a plate developed with hydroquinone covered with comet-shaped markings; it had also frilled.

Mr. W. FEW considered the spots to be the fault of the plate.

Mr. Freshwater handed round a set of bromide prints from the same negatives as the lantern slides he afterwards exhibited.

Mr. Newman showed his detective camera fitted with a changing box for twelve plates; it had an automatic cap for the lens, which it concealed; it was raised by the act of releasing the instantaneous shutter. The camera was also fitted with a focusing adjustment.

Mr. FRESHWATER then gave a lecture on *India*, illustrated by numerous lantern slides projected on the screen. Among these were several which showed the cultivation and curing of the well known Indian tea.

The next meeting will be on Tuesday, May 7, and will be a general technical meeting.

HOLBORN CAMERA CLUB.

APRIL 12.—A discussion was held at the headquarters, 100, High Holborn, on *The Relation of Exposure to Development*.

APRIL 13.—Field day to Richmond, in which a party of members, including two ladies, took part. About twenty plates were exposed with very good results.

APRIL 18.—Demonstration at the Club Room on *The Development of Plates and Making of Lantern Slides*. Several of the latter developed with hydroquinone gave the best possible results.

The following were elected members of the Club:—Miss Austin, Messrs. Lawrence and A. E. Powell.

Friday next, lantern display in the Club Room.

SHAFTESBURY PHOTOGRAPHIC SOCIAL.

APRIL 12.—Mr. WILLS read a paper on *Photographic Shutters*. He exhibited a number of different kinds of shutters and related his experiences in connexion with them.

On the 26th instant the usual monthly Social will be held.

NORTH MIDDLESEX PHOTOGRAPHIC CLUB.

APRIL 8.—Mr. J. Humphries, F.S.A. (President), in the chair.

Mr. EDGAR CLIFTON explained and demonstrated the working of Carbutt's films. After passing round for inspection several films both before and after

coating, also some negatives made on the same one having had six times the proper exposure, the lecturer said that from the earliest dawn of practical photography down to the present time experimentalists have been unceasingly endeavouring to improve the support on which the sensitive compound has to be carried for the purpose of negative making. Starting with the calotype of Fox Talbot, we find that the discoverer of our art appreciated the advantages of a light and flexible film, and accordingly made use of what at that time was the most suitable material to be obtained, viz., pure paper, which he rendered transparent by waxing after exposure and development. This, however, though admirable for large, bold subjects, was soon found to be incapable of rendering the fine detail necessary in small portraits and views, and something more textureless had to be sought for. It may be mentioned that in this process the sensitive salt was formed on the fibre of the paper, which favoured the development of grain in the finished picture; besides this the smallest particles of metallic impurities gave rise to large and disfiguring spots. It is, therefore, not to be wondered at if photographers turned their eyes towards glass as a suitable support and tried various film-forming substances as a vehicle for the iodide of silver, the sensitive salt then mostly in use; of these albumen was the most satisfactory, and many magnificent negatives were made by its use. It had, however, one fatal defect—slowness. While it answered well for architecture and pure landscape, it was practically out of the field for portraiture and the delineation of waves, street scenes, and the like. In 1852 Frederick Scott Archer introduced the collodion process on glass, in which almost the delicacy of albumen was united with a degree of rapidity which (slow as the process now seems) was then regarded as simply marvellous. A contemporary writer said that the sun had merely to wink at the collodion film to impress an image perfect in every detail. But, after all, even collodion, wet or dry, had its disadvantages, and was, after a long series of experiments, displaced by gelatine, in fact by the dry plate of to-day. Collodion on paper had been tried and found wanting, the exceeding tenderness of the film rendering it very susceptible to damage, while its keeping qualities were far from perfect. The tough, horny gelatine film had none of these failings, and almost as soon as it was applied to glass it was applied to paper. The first gelatine emulsion paper of which I can find a record was introduced in 1873 or 1874 by Peter Mawdsley, of Liverpool. Why this did not become immediately popular it is difficult to say. Probably the inventor did not understand the art of advertising his wares as well as the enterprising company who some years later followed on the same lines and once more demonstrated the advantages of a flexible film. The later development of this process, in which the film is stripped from the paper before printing, thus entirely avoiding the appearance of grain, is too fresh in the minds of all present to need further notice, and I will now proceed to the subject which stands against my name on your syllabus to-night, feeling assured that if I do not demonstrate to you a perfect film process I am able to give you something very near it. The plain celluloid film which I now pass round is composed of cotton waste, which, after having been treated with mixed nitric and sulphuric acids, is dissolved with the aid of alcohol and camphor and formed into sheets of suitable thickness; these are then coated with emulsion in the ordinary way, one side of the film being slightly roughened to secure perfect adhesion of the sensitive coating. The emulsion used differs in no way from that ordinarily used, except that its sensitiveness exceeds any plate I have yet tried. There is no tendency to frilling and the coating is remarkably even. There are a few points in connexion with these films to which I should like to draw attention before proceeding to expose and develop a few which I have brought with me. In the first place, the ruby light used to work by must be as safe as it is possible to get it consistent with being able to work in comfort; a thickness of orange paper outside the ordinary ruby lantern will suffice. Secondly, the image must be fully developed or the finished negative will be lacking in density; the development may be watched from the back as with an ordinary dry plate, and the high lights must be plainly visible on the back if full density is required. Thirdly, care must be taken that the film is kept covered by the solution in both the developing and fixing baths or unevenness and stains will inevitably result. And, lastly, the films must be dried on a flat surface or suspended by clips, as the slight expansion of the gelatine may cause them to fall out of the draining rack during the process of drying. He then proceeded to take a portrait of the President, also one of a group composed of members of the Council, upon the films by means of a Hart & Bishop flash lamp, and developed them by hydroquinone.

In reply to several members who expressed surprise at the rapidity with which (for hydroquinone development) the image appeared, he said it was made according to Swan's formulae.

Mr. BRADLEY: There seemed in looking through a negative to be a slight grain; was that real or only apparent?

Mr. CLIFTON: That was the ground surface of the celluloid, which secured the film from frilling. It would not show in the print. He had never known a case of frilling with these films; even tolerably strong hydrochloric acid failed to detach them.

Mr. HINDLEY: Is it possible to print from the wrong side and still obtain the necessary sharpness?

Mr. CLIFTON: They were considered sharp enough when printed from the back, even for mechanical printing.

Mr. BEADLE measured eight films and found that together they occupied three-fortieths of an inch.

Mr. CLIFTON stated that it was necessary to use a glass front to the printing frame to avoid the film curving; he also mentioned that the plain film made a first-class focussing screen, but that, as they could not be bought in that state, anybody wishing to use one for that purpose would have to clean the emulsion from a waste negative.

Next meeting, members' lantern night, May 6.

NOTTINGHAMSHIRE AMATEUR PHOTOGRAPHIC ASSOCIATION.

APRIL 15.—Mr. H. Blandy, L.D.S. Edin. (President), in the chair.

Mr. G. A. BULL (Vice-President) gave an entertainment with his oxyhydrogen lantern, showing one hundred views of Paris, a description of the slides being given by Mons. M. Tuquet.

The attendance was large, there being about one hundred present.

EDINBURGH PHOTOGRAPHIC SOCIETY.

MARCH 6.—Mr. W. T. Bashford (Vice-President) occupying the chair.

Five gentlemen were elected members of the Society.

A note from Mr. Blanc was read, in which he regretted his absence, and stated that he was rather seriously indisposed; and in regard to the representation of the Edinburgh Photographic Society at the forthcoming Art Congress to be held in Edinburgh—a matter in which Mr. Blanc has much interested himself—he requested that the Society should furnish him with the names of three active members of the Society which he would send to the Town Clerk, with the view of their being put upon the list, in case photography might otherwise be unintentionally unrepresented.

The Society, acting on this suggestion, elected their President and Vice-Presidents as their representatives.

Mr. R. H. Bow, C.E., F.R.S.E., then read two papers, *A Second Note regarding Stands by means of which Lantern Slides may be Satisfactorily Seen* [see page 286], and a note *On the Binding or Framing of Lantern Slides* [see page 285].

At the conclusion of each paper, the Society took the opportunity to comment most favourably on the nature of the communication. A hearty vote of thanks was accorded to Mr. Bow, and the Secretary was authorised to illustrate the notes in the billet.

Mr. J. T. LEIGHTON followed with the exhibition of his recently designed "Photographoscope." Mr. Leighton thus described his invention:—"The 'Photographoscope' is a novel apparatus for displaying photographs or other pictures, giving them all the advantages of a frame setting, and at the same time allowing them to be changed at will. In appearance the apparatus resembles a handsomely designed frame and suitable mount laid against an ornamented shield. The design is capable of a large amount of elaborate and artistic ornamentation, and the apparatus forms a most attractive feature in the household, and is also particularly adapted for the studio or saloon of a photographer. By turning a small side knob or handle the pictures appear one after the other in endless succession, the one in view falling back and making way for another coming forward, and so on as long as may be desired, a fresh picture appearing at every revolution of the handle. The two designs shown were each capable of accommodating twenty-one prints, but the number of prints is only limited by the size of the apparatus. The 'Photographoscope' is very simple in construction, and not in any way liable to get out of order. By its use the photographs are completely protected from dust and the effects of the atmosphere, and also from the effects of handling and rubbing together, so destructive to valuable prints. The pictures in the 'photographoscope' being viewed one at a time, and in a frame, give them a fairer opportunity of having their merits appreciated than is the case when several are before the eye of the observer together.

The ingenuity of Mr. Leighton's exhibit was thoroughly appreciated, and he was heartily thanked for bringing his apparatus before the notice of the Society.

DUNDEE AND EAST OF SCOTLAND PHOTOGRAPHIC ASSOCIATION.

APRIL 11.—Mr. John Robertson (President) in the chair.

Messrs. Harben, Valentine, and D. Owens were elected members.

The following were declared the prize winners in the lantern competition:—1st, V. C. Baird; 2nd, A. Wilson; 3rd, R. C. Henderson.

The American Exchange slides were exhibited.

Mr. J. ROBERTSON drew the members' attention to Patent, No. 1461, "Improvements in Photographic Transparencies," the specification of which appeared in THE BRITISH JOURNAL OF PHOTOGRAPHY of the 29th ultimo, and which he stated was invalid and could be practised without fear of infringement, his argument being supported by the production of a transparency made by him on similar lines nearly twenty years ago.

A small committee was appointed to make arrangements for three outdoor meetings during the summer, the first to be held on the Queen's birthday.

Correspondence.

Correspondents should never write on both sides of the paper.

RAILWAY FARES AND PHOTOGRAPHIC SOCIETIES.

To the Editor.

SIR,—I would like to call attention, through the medium of your valuable paper, of the photographic societies to the advisability of agitating the railway companies for the granting to members of photographic societies fare and a quarter tickets. This privilege has been enjoyed by a fishing club for some years, and why not amateur photographers? I believe the Liverpool Society, some two or three years since, did take this question up, but do not remember with what results. If the Camera Club would now take the initiative, and invite the co-operation of all societies, sufficient influence might be brought to bear upon the railway companies as would induce them to grant the concession. Trusting some more able pen than mine will take this question up—I am, yours, &c.,

P. E. KNIGHT,
Hon. Sec. Notts Amateur Photographic Association.

NEW SOCIETY.—THE BRADFORD PHOTOGRAPHIC CLUB.

To the Editor.

SIR,—Will you kindly announce the establishment of a new society in Bradford, "The Bradford Photographic Club," which dates from the first of the present month, and state that our dark rooms and other

conveniences are at the service of members of societies of other neighbourhoods visiting this town?

The officers are as follows:—*President*: Mr. Charles Holmes.—*Vice-Presidents*: Messrs. G. D. Scorrab and C. W. Wade.—*Committee*: Messrs. N. Scott, H. Gibbs, E. Wade, J. S. Douglas, W. Judson, J. Cotton, M.I.M.E., and W. H. Hall Ward.—*Treasurer*: Mr. John S. Swithenbank.—*Hon. Secretary*: Mr. Frederick North.

The rooms are at 27, Kirkgate, Bradford, and the Hon. Secretary, having his private office at the same address, will be pleased to receive visitors there, where intending members may receive every information pertaining to the Club, and any of the photographic brotherhood being strangers to the town may find a haven.—I am, yours, &c.,
27, Kirkgate, Bradford, Yorkshire, April 17, 1889. FREDERICK NORTH.

THE YORK EXHIBITION.

To the Editor.

SIR,—I have for some time past taken great interest in the subject of photographic exhibitions, because I think they are destined to greatly influence the future of photographic art. And I regret to find, from the conditions and rules for the forthcoming exhibition at York, that the charges for amateur exhibitors are such as are, in my opinion, likely to deter some from contributing. I hope this may "meet the eye" of those "whom it may concern," for I should indeed be sorry if the exhibition at the capital of my native county should be in any respect behind similar gatherings of pictures elsewhere.

1. With regard to charges for wall space, I read the rules to mean one shilling and sixpence per square foot, with one shilling per frame for unpacking and repacking, &c. I take it that the amateurs' frame will average somewhere about two square feet, so that the cost per frame will be about four shillings. Suppose one to contribute half a dozen frames, scattered about among the six amateur classes; these would cost (when packing, care, and carriage were paid for) something not far short of thirty shillings; and I fancy that amateurs living at a distance will think twice before deciding that "the game is worth the candle." The professional exhibitor, perhaps, may be said to regain some part of his "charges" in the form of advertisement, and the longer the exhibition is open the greater the gain; but this will not apply with equal force to the amateur, who, on the contrary, may consider the length of time—June to October—as a disadvantage.

2. Is Class I., Division A., confined to pictures which have already gained medals elsewhere?

3. In Rule 5 (*re amateurs*) "the negative must have been exposed, developed, and printed by a *bona fide* amateur."

Does this include or exclude the retouching?—I am, yours, &c.,

Cambridge, April 20. F. C. LAMBERT.

VALUATION OF QUINOL.

To the Editor.

SIR,—In your abstract of Professor H. Foster Morley's paper on *Hydroquinone and its Uses as a Developer*, read before the University College Photographic Society on the 9th instant, the author is reported to have said that the quantity of potassium permanganate absorbed by a solution of quinol in an acidified boiling solution "corresponds to a consumption of eight atoms of oxygen by each molecule of the permanganate." This last word is evidently a mistake (possibly a printer's error) for quinol, while eight atoms of oxygen should read ten atoms.

I believe I was the first to publish (in my letter to you of the 25th ultimo) the fact that ten atoms of oxygen are absorbed by each molecule of quinol in a direct titration with permanganate in a boiling acid solution. As a matter of fact, Dr. Morley's figures confirm my own result, as he states that six milligrammes of quinol require 11.3 c.c. of decinormal permanganate, 10.9 c.c. corresponding to ten atoms of oxygen, and 5.7 c.c. to eight atoms respectively.—I am, yours, &c.,

I. H. SMITH, Ph.D., F.I.C.

Mawson & Swan's Laboratory, Low Fell, Gateshead, April 20, 1889.

FLASH LAMPS.

To the Editor.

SIR,—I do not know what I have done to Mr. Hart to bring down upon me his wrath. At first I had intended not to have noticed his letter to you, but I do not understand what he means by making me the author of such silly remarks as using heated hydrogenous vapours to oxy-lise metals. I never made any such stupid remark; in fact I do not know its meaning, neither does Mr. Hart probably. With regard to his multiple distributor, such a wonderful and costly apparatus is not at all necessary. An ordinary pneumatic ball will flash several lights simultaneously and quite as effectively. I have taken groups at several photographic meetings, some of which contained nearly forty persons, and never failed but on one occasion, and that was when Mr. Hart himself used his lamps and multiple distributor at a meeting at which I attended to take a picture. I may add, I had no idea at first of producing these lamps, but so many photographers were pleased with their simplicity, cheapness, and effectiveness, that I was induced to do so. Apologising for troubling you—I am, yours, &c.,
W. ENGLAND.

AMATEUR VERSUS PROFESSIONAL.

To the Editor.

SIR,—In anticipation of a threatened attack upon my position here and in England as a photographer, may I beg of you to state in the columns of your valuable and widely-read JOURNAL that I *entirely* disclaim pretensions to "posing as an amateur?" I put my work on the open market, and am therefore a *professional*, though inexperienced. My name does not appear on the list of London workers as yet, but on my return to England this step will be taken. Thanking you, in anticipation, for inserting this appeal for fair play—I am, yours, &c.,

GEORGE J. S. GRAHAM-FOLER.

Santa Cruz de Tenerife, Canary Isles, April 4, 1889.

ILLUSTRATIVE PHOTOGRAPHY.

To the Editor.

SIR,—My attention has been called to your issue of April 12, containing an article on *Illustrative Photography*. The statement therein contained as regards *Punch* is incorrect. As the engraver for that periodical, I am in a position to declare that the whole of the illustrations are engraved upon wood, and always have been so produced.—I am, yours, &c.,
JOSEPH SWAIN.

6, Bouverie-street, Whitefriars, E.C., April 18, 1889.

Exchange Column.

* * No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

Wanted, background in exchange for books by Professor Tyndall.—Address, J. B., 4, Carlton-terrace, Harrow-road, W.

Would exchange handsome tall-case hall clock, chimes quarters on eight bells, for modern large-sized camera and lens by good maker.—Address, WATERMAN, Photographer, Shanklin.

Will exchange two dozen bromide opals (half-plate) for contact printing by gas, in perfect condition, never been opened, for one dozen 8½ x 6½ Mawson plates.—Address, H. H. ARMSTRONG, Pelaw House, Chester-le-Street.

Answers to Correspondents.

* * Communications relating to Advertisements and general business affairs must be addressed to "H. GREENWOOD & Co.," 2, York-street, Covent Garden, London, W.C.

All matters for the text portion of this JOURNAL, including queries for "Answers" and "Exchanges," must be addressed to "THE EDITOR," 2, York-street, Covent Garden, London, W.C. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.

PHOTOGRAPHS REGISTERED:—

H. R. Smyth, Weston-super-Mare.—Photograph of Thomas Palmer, only survivor of the battle of Corunna.

J. Stuart, Glasgow.—Photograph of the Right Hon. the Earl of Aberdeen.

Alexander Stuart, Clydebank.—Three photographs of the interior of the Iman and International Company's T.S.S. "City of Paris," and T.S.S. "City of New York."

A. FOSTER.—1. Any of the ordinary emulsions will answer for development printing.—2. The coating should be somewhat thin.

SENSITIVE.—Dissolve nitrate of silver in distilled water in the proportion of sixty grains to the ounce. Nothing more is required.

A. SQUIBB.—Tartaric acid has been found by some to be an improvement upon citric acid as a means of preventing the yellow discolouration of sensitive paper.

J. J. P. B.—We cannot throw any light upon the cause of these spots, which seem at the present time to be molesting photographers to a greater extent than hitherto.

Y. A.—The beveled-edge opal plates may be obtained of any glass merchant who makes photographic glass a speciality, also from most photographic material dealers.

H. B. HART.—1. The publishers of Burton's *Photo-mechanical Printing* are Marion & Co., Soho-square.—2. England Brothers, St. James's-square, W., publish Wilkinson's works.

CONSTANT READER.—The answer in question was not inspired by the gentleman named. You will, however, find him to be a most reliable mentor, and you cannot do better than follow his directions.

X. Y. Z. is anxious to learn where he can obtain photographs of natives of Africa to illustrate costume of the different tribes, &c. Perhaps some reader will kindly enlighten our correspondent.

WORK.—Sorry we cannot give you any information relative to the obtaining of copies of tracings in black lines on a white ground in one operation, such as that which can be effected in blue lines on a white ground.

J. H. G.—1. There should be no stain if the plates were properly washed, but there is no way of removing it now.—2. No stain should be produced with any of the recognised reducers. Stains are the result of careless manipulation.

LITHO.—You will have to get the drying closet made to order, as it is not an article of commerce. You will also have to design it yourself, as there is no recognised form; each worker has his own pet pattern and of a size to suit his requirements.

A. Z.—The reply you received is certainly very funny. The letter was evidently answered by a clerk who has no practical knowledge of the business. Better write personally to one of the principals. Comical as the letter is we cannot give it insertion in our columns.

C. G. K.—For retouching, Redmond Barrett's *Art of Retouching*, which was published in our pages of 1886, commencing with the number for August 6. It forms one of the most complete treatises on the subject that has yet appeared. For enamelling you cannot do better than adhere to the directions on page 477 in our ALMANAC for 1888.

GALWAY.—We have no idea where focussing screws for cameras are made, but, seeing that you require a number of them, would suggest that you place yourself in communication with some firm who supply mechanics' tools and order a set of die-stocks with double-threaded screws, by which you could make them yourself if you have a turn for mechanics.

WATTY says, in taking an interior the other day, a window at the side of the church is shown faintly in the negative, although this window could not be seen on the focussing screen, and he is sure that the camera was not moved while the lens was uncapped.—The second image is due to a minute hole somewhere about the camera which has operated as a "pinhole camera."

W. THOMPSON asks the proportion of benzole to be added to the solution of gums in ether to make a good matt varnish?—This all depends upon the opalescence desired. The larger the proportion of benzole the more opaque and coarse will be the film, and the less the finer and more transparent. The best plan will be to add the benzole in small quantities at a time, testing the varnish after each addition until the result desired is arrived at.

REV. J. C. BROWNE (Thurning Rectory, Oundle) writes: "Some time ago I bought a dinner service in Manchester; the shop is closed now and vendors gone. I am wanting more of the same pattern. One mark on plates (under side) is 'O. H. E. C. (L4)'. Can you kindly give me an idea of the meaning of these initials? If any of 'ours' can assist me I should be greatly obliged. And does any one know if this Company burns in photographs?"

W. H. WARNER.—Our correspondent directs our attention to a simple but efficient shutter introduced by a local optician by which clouds can be taken in conjunction with the landscape, and trusts that we may think well enough of it to recommend it.—Unfortunately, we are entirely ignorant of its nature or construction, nor can we find it in any catalogues of London dealers to which we have referred. Will Mr. Warner kindly send us an account of its construction?

J. SCGG says: "Recently I made up a toning bath according to the acetate formula, and it became turbid as soon as mixed, and the next day there was a dirty deposit at the bottom of the bottle. Although I used a fifteen-grain tube of chloride of gold it would not tone at all. What is the reason?"—The reason is that from some cause or other the gold has been precipitated; possibly from some impurity in the water, or perhaps from its being put into a dirty vessel.

STEREO writes asking how he can make paper photographs transparent, like some old French stereoscopic slides he saw many years ago.—The pictures can be rendered transparent by saturating the paper with wax; the bleached wax should be used. Place the print on an iron plate sufficiently heated to melt the wax. Rub the wax over the print until the paper is thoroughly saturated. Then place it between sheets of clean blotting paper, and iron with a tolerably hot laundry iron to remove the surplus wax. In place of wax solid paraffin may be employed.

GEORGE writes as follows: "I am erecting a studio in my garden for taking portraits. Ours is a private road, and my neighbours on either side are threatening to prevent me from commencing business there. Have they the power to do this?"—If there is no clause in our correspondent's agreement with his landlord prohibiting a business being carried on on the premises we do not think he can be stopped. Certainly the neighbours cannot interfere so long as the studio does not stop light and air from their premises, and the business is carried on so that it causes no annoyance.

N. S. D. writes: "1. I have a silver bath (sixty grains to the ounce) which I have not used for more than a year; I find that the nitrate of silver has found its way through the cork of the bottle (I used a cork, not a glass stopper) and crystallised, and there is a dark stain or deposit on the inside of the bottle, although the solution itself seems clear enough. If I filter it and strengthen the bath will it then be safe to use?"—2. Is a license required to retail chemicals (for disinfecting purposes), such as permanganate of potash, &c.?"—In reply: 1. The bath will doubtless work all right after being filtered. The probability is that it will not require to be strengthened.—2. No license is required.

E. J. W. inquires: "Is it possible to take quarter-plate negatives with a hand camera and to enlarge these to (say) whole-plate size, and obtain prints nearly equal in quality to those from negatives the size of the print? In other words, can such enlarged prints be made of a quality that one with a love of good photographs would care to put in his albums? All that I have seen have been flat and fuzzy, more or less; but I have few opportunities of seeing such things."—Reply: It is not only possible to enlarge from quarter-plate negatives up to whole-plate size, but it is done in innumerable cases. The quality of the enlargement depends, of course, upon the excellence and sharpness of the negative.

KODAK.—1. The lens named will answer well when the screen is a considerable distance away from the lantern.—2. The 2B of the same maker will answer better, because its focus is shorter, but for general work one of still shorter focus is preferable.—3. The flare spot in your portrait lens may be ameliorated, although not entirely got rid of, by placing the diaphragm in front of the front lens instead of its present position.—4. To ascertain the focus of the front lens, unscrew the cell and use it convex side out as a burning glass, then measure the distance between the outer surface and the solar spot. This, of course, will only give you a rough idea of the focus, but will be sufficiently near to aid in the construction of a camera. Unless we had the lens for examination we could not give you nearer particulars.

C. M. MAJOR.—Without answering your queries *seriatim*, we may state that your C.-D.-V. lens possesses too short a focus to reproduce a negative 12×10 from a transparency the same size, but if it were a case of making a small negative from that transparency it would answer admirably. The actinic triplet or doublet referred to would certainly answer better, their focus being so much longer. For ordinary enlarging or reducing the C.-D.-V. lens answers well, but to obtain the best effects when working with it, it is necessary that the back lens of the portrait combination must always point towards the image the dimensions of which are the smallest. When reproducing the copy on the same scale as the original (a thing we often do) we focus sharply with a medium stop, and then insert a stop sufficiently small to make the marginal definition crisp.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting, May 1, 1889, will be on *Weights and Measures*. Saturday afternoon outing will be at Totteridge. Train from Broad-street at eight minutes past two.

We have received the *Photographic Annual and Catalogue* of Jonathan Fallowfield. This catalogue is replete with most of the varieties of photographic goods in the market and contains upwards of three hundred pages. It is an imposing volume and arranged with taste.

WEST LONDON PHOTOGRAPHIC SOCIETY.—The last ordinary meeting (for this session) of the above will be held at the Addison Hall on Friday, May 3, instead of April 26, as announced; and on Friday, May 10, there will be a smoking concert, at eight o'clock, in the Richmond Hotel, Shepherd's Bush-road. It has been arranged to hold outdoor meetings on the last Saturday afternoon of each of the summer months, commencing on May 25. Members are invited to suggest to the Secretaries suitable places in the neighbourhood of London.

ON April 16, at the meeting of the Photographischen Gesellschaft in Vienna (one of the largest and oldest photographic societies on the Continent), a large number of landscape pictures by Mr. Harry Tolley, of Nottingham, were on exhibition. The leading professional photographers closely examined them and agreed in declaring them to be some of the finest specimens of artistic photography, and well calculated to sustain the high reputation which English photography enjoys on the Continent. Professor Luckart, the Hon. Secretary, himself a celebrated artist, publicly expressed his admiration of their great artistic merit, and in so doing carried the entire meeting with him. On the same occasion was shown a continuation of a series of beautiful works by Messrs. Green Brothers, of Grasmere (the others had been exhibited at the previous meeting). These excellent platinotypes likewise received the praise they so well deserve. These pictures, the one set amateur, the other professional work, are here going the round of the societies.

DEATH OF MR. WARREN DE LA RUE.—The death of Mr. Warren de la Rue, D.C.L., Ph.D., F.R.S., &c., occurred on Friday evening, the 19th instant, from pneumonia, after a short illness. The deceased gentleman, who had attained the age of seventy-four, was born in the Isle of Guernsey, and was educated at the College of St. Barbe, Paris. Records of his many scientific labours will be found in the *Transactions* of the Royal Astronomical, Chemical, and other societies. The principal work in which he distinguished himself was the application of photography to the recording of celestial phenomena. The photographs, when measured by a micrometer which he invented, furnished exact astronomical data. He established a private observatory at Cranford, Middlesex, but it was dismantled in 1873, and the instruments presented to the University of Oxford, where they have been employed lately most successfully by Professor Pritchard in determining, by means of photography, the distance of sixty-one Cygni and other fixed stars. He held office in several societies. For some time he acted as Honorary Secretary of the Royal Astronomical Society, of which he was also President from 1864 to 1866. He was President of the Chemical Society from 1867 to 1869, and again in 1879-88, from which time he acted as one of its Vice-Presidents. For many years he was President of the London Institution. In 1878 he became Secretary of the Royal Institution, on the retirement of Mr. Spottiswoode, who was elected President of the Royal Society, but resigned the post in 1882. In commercial life he was a member of the firm of Thomas de la Rue & Co.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1513. VOL. XXXVI.—MAY 3, 1889.

THE STRENGTH OF ALKALINE SOLUTIONS.

THE gradual coming into favour of the carbonates of potash and soda, and, since the popularisation of hydroquinone, of those two alkalis in the caustic state, has rendered it more than ever incumbent on the photographer who wishes to keep himself acquainted with what he is doing to have some ready means of estimating the strength of the solutions he employs with at least moderate accuracy. This is the more necessary in view of the widely differing formulæ that are given with different plates, no less than of the equally varying opinions expressed as to the relative value and behaviour of the several alkalis. It stands to reason that any operator who is in doubt as to whether the formula he is employing is the one best suited to his plates should, in trying another against it, do so, as far as possible, under identical conditions, and this he can only do if he knows precisely the comparative alkalinity of his solutions.

The mere mention of the necessity for such care may perhaps raise misgivings in the minds of some of our non-chemical readers, whose acquaintance with the operations of quantitative analysis generally, and of alkalinity in particular, is of so limited a nature as to make the mere mention of the proposed task a terror. But the difficulty to be encountered in securing the degree of accuracy needed for our purpose is really not such as to deter any one from making the attempt who has sufficient intelligence to successfully accomplish the development of a plate.

Of course the work will be more easily performed and with closer accuracy when proper apparatus or appliances are at hand, though these need not be of an elaborate or expensive character; but a truer and more systematic acquaintance with the real value of some of the very variable compounds, such as sodium and potassium carbonates, than can possibly be derived from their theoretical composition can be obtained with no more elaborate apparatus than are to be found in every photographer's laboratory.

The method to be followed will be, whether with or without special apparatus, that known as the volumetric, in which a weighed quantity of the substance to be examined, or a given volume of its solution, is tested or "titrated" by means of a standard solution of any convenient acid whose saturating power is accurately known, a small quantity of tincture or solution of litmus, or other "indicator," being employed to determine the exact point of neutrality.

As regards apparatus, all that will be requisite will be a burette, preferably of the form known as Mohr's, which consists of a graduated glass tube, holding twenty-five, fifty, or one hundred cubic centimetres of liquid, each division being sub-

divided into five or ten parts, and fitted with a glass tap, or a specially arranged delivery tube with spring clip, to permit small quantities of the solution to be drawn off at will. A stand or holder for the burette and a glass flask or two in which to perform the test complete the outfit.

The test acids ordinarily employed are sulphuric, hydrochloric, or oxalic. The two first are objectionable to the inexperienced chemist, inasmuch as they themselves have to be accurately estimated before anything like a "standard" solution can be made. But oxalic acid, if obtained of the quality sold as "pure" and from a good source, is a tolerably definite article, and may be taken to be what it represents. A convenient strength to employ will be formed by dissolving one-tenth of a gramme-atom, as it is called, of the acid in 1000 grammes or one litre of distilled water. The "gramme-atom" is the number of grammes represented by the combining equivalent of the substance, and the standard solution of oxalic acid will therefore consist of 12.6 grammes of the pure crystals made up to a volume of exactly one litre with distilled water.

Grains and fluid grains, or "grain measures," may be used instead of grammes and cubic centimetres if preferred, and if the instruments can be obtained thus graduated; but the majority of burettes are divided into cubic centimetres. But as the actual size of the division is purely arbitrary, so many grains of the solid material may be dissolved to form one litre of solution, and the burette will then deliver it in accurately divided portions, each division on the scale representing one-thousandth of the whole quantity. In this case, owing to the difference between a gramme and a grain, it will be advisable to dissolve 126 grains of the acid in order not to have too delicate a solution.

The litmus solution had better be procured ready for use at one of the operative chemist's, as ordinarily supplied in the crude state it contains a considerable quantity of alkali, and requires very careful adjustment before it is of any use for our purpose. There are other more fashionable and newer indicators, but the one named will answer every purpose.

In order to make a test, let, say, one gramme (or ten grains) of the substance to be tried be dissolved in any convenient quantity of water, and one-tenth of this solution taken to be operated upon. Or if a stock solution of the substance be already made and require testing, take one drachm of it and dilute it to any convenient volume, again taking one-tenth for actual trial. This lessens the chance of error in weighing or measuring small quantities. To the solution to be tested add a few drops of the litmus solution, sufficient to give it a decided blue tinge when thoroughly mixed.

Next, fix the burette in the holder and see that the tap or delivery clip acts properly; fill it with the standard solution, and let this run back into the bottle to remove any traces of moisture. Refill, and carefully, by means of the tap, let the surplus run out until the surface is level with 0 or zero—the numbers, be it remarked, progressing in the downward direction. Arrange the height of the burette in its holder so that its delivery tube comes nearly down to the level of the neck of the flask containing the alkali. Now commence by allowing a few drops of the test solution to run into the flask, and mix thoroughly; at this stage probably no change of colour at all will be noticed, in which case a fresh quantity is added. It may be, however, that if the quantity of alkali is very small a red colour is produced, which, however, disappears again on mixing; when this occurs great care must be taken to make further additions very gradually, using at the critical stage a single drop only at once, and mixing the contents of the flask thoroughly after each such addition, continuing until a permanent red tinge is given.

But it is only in the case of the caustic alkalies that the procedure is so very simple. When the carbonates are in question the carbonic acid is expelled from its combination with the alkali part of it, escaping in the form of gas, and a portion remaining in solution and giving a reddish tint to the solution some time before the point of neutrality is reached. The colour is, however, quite different from the full red given by the faintest excess of oxalic acid, possessing more of a purple tone. To get rid of this disturbing influence the contents of the flask must be boiled, or at any rate heated for a short time over a Bunsen or spirit flame, when the blue tint will return, and more test solution must be then added, until after repeated heatings the full red tint becomes permanent. Turmeric tincture may be used instead of litmus, as, though not so sensitive, the sudden change from deep brown to pale lemon yellow is far more recognisable to inexperienced eyes, besides which it is inert to carbonic acid, and therefore obviates the necessity for boiling in the case of carbonates.

When the neutral point is reached it is only necessary to read off the number of divisions and fractions of solution employed, and from these figures the actual quantity of alkali can be calculated by the tables at the end of our ALMANAC.

In the absence of a burette a minim measure and a dropping tube may be used, filling the former to start with, and refilling if needful, deducting the quantity finally remaining from the total poured into the graduate.

PRACTICAL CONSIDERATIONS IN STUDIO BUILDING.

(Concluded.)

AFTER discussing the glass roof and sides, all the salient points of the subject will have come under review, and this last topic may be said to be one upon which as varying and contradictory views are held as upon any one part of the design of the fabric. Taking first the rafters or framework, they are made of all sizes and thicknesses and materials—wood, iron, zinc, &c.; but modern studios have radically different needs from those built over half a score of years ago. In those times advantage was sought to be obtained of every trivial gain of light possible, and metal, strength for strength, obstructing so little light in comparison with wood, was often chosen for that point alone, without regard to any other consideration. The rapidity of gelatine plates, however, has now completely altered the

case, and the photographer who builds a studio is able in most instances to disregard the actual space occupied by his skylight frames and to choose what will be substantial and useful rather than light. The best advice he can follow in this connexion is to have the woodwork of his skylight thoroughly strong and rigid, there is then less strain upon the cohesion of glass to frame, either through the action of weather and temperature, or the weight of the workmen when the services of the inevitable painter and glazier come to be required. To this end we perhaps need scarcely point out that depth rather than width of rafter is what is needed to give stability, though, unfortunately, where the amount of light is of moment the depth of the bar rather than its width is the chief obstructing element. A word of warning will be useful here. Thorough consideration should, before building, be given to the subject of ventilators needed. Glass roofs, at their best, are always most difficult to keep water-tight, and the most effective way of preventing their being so is the knocking and shaking always necessary when alterations have to be made to obtain additional ventilating conveniences, a state of affairs of most frequent occurrence. The size of the rafters must of course be governed by the pitch of the roof and the width of the sheets of glass it is decided to employ. Obviously the larger the sheets the smaller the number of these light-obstructors necessary. There is a limit here, except plate glass is employed—namely, the maximum size of the sheets as manufactured. Many of our professional friends prefer plenty of length rather than breadth, so as to avoid the unsightly streak of dirt that forms at the junction of the pieces. This, however, may be, and in at least one studio at present in use is, got rid of by painting a broad strip of the glass at the junction with some solid dark paint, which entirely hides the unseemly collection of dust and dirt and does not rob the studio of any practically available light. The effect of this is a great gain in appearance.

We do not propose to discuss such arrangements of lights as the “zigzag” or “alternate” form, which was patented some years ago, the object being to avoid loss of light by reflection of a considerable portion of the rays received at an oblique angle, as happens under ordinary conditions. The plan was more ingenious than useful, space was unnecessarily taken up, and the cost greatly increased. So far as regards the shape of the supports for the glass; next to consider is the glass itself. Sheet glass, plate glass, rolled, fluted, plain, or roughened on the surface—“obscured” or “smoothed,” as it is termed—white glass, ordinary green glass, and glass coloured pale blue by Cobalt, have all been used, and the superiority of each lauded; Cobalt glass is not now employed. Sheet glass is most commonly adopted, while polished plate is of rare occurrence on account of its great cost. Further, some samples are very liable to change in colour, as may be seen in many a shop window, panes of glass, originally almost colourless, having become purple or yellow after a lapse of time. Sheet glass when clear will, then, be most in demand, and in view of meteorological eventualities it should always be of substantial thickness; “fifteen ounces” or “twenty-one ounces” is certainly too thin, “thirty-two ounces” is costly but the extra outlay will be well spent money, one short half hour of hailstorm, such as occasionally visit these islands, being capable of doing more injury to the content of the studio than many times the cost of the glass would cover.

When, however, it is decided to use obscured glass, this

ribbed plate is as cheap, and far preferable on account of its freedom from the curvilinear shape so often characterising thick sheet.

The question as to whether obscured glass or clear should be used is one not capable of solution in a general way, though in particular instances there is no doubt. A more uniform light is secured by the use of roughened or surface ground glass; but with a clear sky-view there is on the whole much loss of light to the sitter. "Is the latter disadvantage counterbalanced by the gain in softness, &c., obtained by the even and regular illumination from obscured glass?" is the query that presents itself. The reply, as we say, cannot be predicated exactly. Clearly it is an advantage to have plenty of light; for if it be in excess it can always be diminished by screens, while if in defect at the outset the loss cannot be made good. That some operators prefer the softness and risk the loss of light is proved by the fact that studios are in use now in which the whole of the glass has been permanently covered with tissue paper by the photographers who work in them. Each photographer, then, will decide for himself, except in cases where the skylight to be glazed lies between a building or dead wall and the sitter. In that case an obscured glass is a very great gain, as a portion of the light received is by its means sent to the sitter instead of passing through and illuminating, and being almost wholly lost in the room itself instead of the sitter. It may here be pointed out that glass employed by grinding with sand, &c., has the disadvantage of gradually becoming soiled-looking and incapable of being brought to a state of pristine whiteness.

It does not form part of the plan of this series to describe the various modes of fastening the glass *in situ*, other than by the usual means of putty and paint; but as regards the latter, a wrinkle of great value may be given. Let the margin of every sheet of glass, before being bedded in its place with putty, be painted on each face with a thin strip of paint about half an inch wide, which is then allowed to set before the panes are placed in position. This done, and the rafters first coated with paint before glazing (and no glazing ought ever to be permitted before this is carried out), the chance of the everlasting "drip" in wet weather, common to so many studios, will be almost reduced to nil.

We now conclude this series of articles, merely observing that all the advice given is the result of the experience of many practical men whose knowledge we have not failed to draw upon to illustrate our own experience.

THE Paris Exhibition is being rapidly pushed forward, though it will, probably, be far from completed by the opening day. British photography will be well represented, though not on such an extensive scale as was at one time anticipated. English photographers visiting this exhibition will not find themselves so much behind their confrères across the channel as they did in the two previous ones. Both in the 1867 and 1878 shows the Continental portraiture was much ahead of the British, now the latter can hold its own against it. English photographic apparatus—both in optical and cabinet work—has always been in advance of that produced abroad, and the forthcoming exhibition will prove that this supremacy is still maintained. It is in the mechanical processes of photography alone that we anticipate England will appear at a disadvantage.

PHOTOGRAPHERS who desire to secure effects which can only be obtained at certain seasons should ever be on the alert. Missing the chance when it presents itself often means having to wait for twelve

months before the opportunity can possibly occur again. Last year spring, it will be remembered, so far as early foliage effects were concerned, was of shorter duration than usual. This year it promises to last longer, unless we happen to experience an unseasonable change, no unusual circumstance by the way in this variable climate of ours. In many parts of the country the trees and shrubs are already putting on their spring garments, so that those who desire to secure negatives of early spring effects should be prepared, or they may, possibly, have to wait another year before they will again have the opportunity.

THERE are many subjects which cannot be taken when the trees are in full leaf, except under great disadvantage pictorially. Notably is this the case with many buildings and ruins with trees in close proximity; either the picture must be taken from within the trees with a wide-angle lens, or we must put up with the most interesting portion of the subject being obscured by them. If the picture be taken when the trees are devoid of foliage, although the subject is fully shown, it always has more or less an unpleasant look. If, however, the picture be secured when the leaves are just budding forth the whole aspect is different, while the principal subject is fully depicted, the picture does not bear that dreary appearance as if it were taken under wintry conditions.

MANY excellent pictures may be obtained in glens, plantations, and woods while the shrubs and bushes are wearing their spring garb, which, later on, would not be worth taking. The tints on the delicate foliage when the sun is playing upon it makes a glorious scene, although there may be nothing particular in the subject, which is very effective in a photograph. Pictures of this character as lantern slides, when projected upon the screen, rarely fail to meet with approbation. There is another class of subject that can only be effectively rendered at this season, namely, certain trees with their knarled and rugged branches. If such subjects were taken when the tree is covered with leaves much of the picturesqueness would be lost, and if taken when the foliage is off the trees would have a barren and dead appearance. But if, on the other hand, the negative be secured while the leaves are still small and in a good light, life is given in the picture, while the most interesting portions are as clearly depicted as if the trees were entirely free from foliage.

A CORRESPONDENT, writing anent the "mysterious spots" which sometimes make their appearance on freshly made prints, says, in his case, he has traced them to the prints being sometimes dried in a room the walls of which have recently been papered with paper embellished with bronze powder. He imagines that particles of the bronze become detached and settle on the prints while they are wet. If this be the origin of spots, it shows what unsuspected causes may, and possibly often do, result in injury to the delicately constituted image of an albumenised paper picture.

THE Board of Trade inquiry now proceeding on the question of the electric lighting of London is one of some interest to the photographic profession, more particularly if it results in a greater extension of this system of illumination. There is no question that a large number of professional photographers in all parts of the metropolis, and indeed in most other towns, would gladly avail themselves of the electric light as an auxiliary to daylight during dark and foggy weather were it not for the cost of the plant for generating the electricity. In some parts of London the current can be had from mains, but the districts where it can be at present very restricted.

APART from the cost of an engine and dynamo, a current supplied like gas and always ready for use is far more convenient, and, we hear, some who have an installation of their own have discontinued its use and are now employing a current from outside sources. With the electric light much waste time on dull days may be profitably employed in photography, quite apart from ordinary studio work. It is to be hoped that the inquiry, now pending, will lead to a more general supply of electricity in all parts of the metropolis.

GREAT is the debt of gratitude owing by photographers to Mr. John Carbutt, of Philadelphia, for his application of celluloid films to photographic use. Soon after their introduction we received a sample packet from Mr. Carbutt, and were quite charmed with them. Transparent films are becoming an institution in this country, and, in addition to the quantities imported ready sensitised from America, are also now being coated here. Through one firm (the London Stereoscopic Company) the demand has been so enormous that the supply has temporarily fallen short, but we knew that Carbutt's factory is equal to any strain which may be made upon it, and that the equilibrium of supply and demand will be established without any delay. In a note from Mr. Carbutt this gentleman informs us that he has devised an effective film carrier for the camera, but not having seen any description of it, we are as yet unable to speak concerning this *desideratum*. From Messrs. Fry & Co. we have a sample of home-coated celluloid films which sustain their reputation. This firm works under the American patent, which is in force also in Great Britain.

It is a regrettable circumstance that many photographs are printed on paper which will ultimately change in colour. In the recent exhibition at the Crystal Palace there was a gigantic carbon enlargement which had evidently been made for a very long period, for the whites had become quite yellow, although the pigment composing the image was apparently unchanged. Many collotypes are printed on paper which, with exposure to light, will become discoloured, and, if they be of a photographic colour, they assume very much the appearance of fading silver prints. If, however, they are printed in an ink of an engraving colour the change in the tint of the paper is less objectionable.

A GREAT deal of the varnish used for glazing collotypes to give them the appearance of albumen prints turns yellow with age. When this occurs the pictures closely resemble silver photographs in a state of decay. A permanent image on an unstable base is a very undesirable condition in any photographic process.

THE deterioration in the colour of paper is due to the material used in its manufacture. At one time only linen or cotton rags were used. Now certain grasses, straw, wood, &c., are largely employed as a cheap substitute, all of which are liable to change in colour with exposure to light. It may not be generally known that if a piece of freshly planed deal board be exposed behind a negative to sunlight for a few days that a distinct impression will be obtained. A similar result will accrue with some of the commoner kinds of paper, most of which are extremely sensitive to the light's action. Notably is this the case with some of the wood fibre boards used for the middles of photographic mounts.

THE WHOLE ART OF PHOTOGRAPHY IN A SERIES OF EASY PROGRESSIVE LESSONS.

[THE series of *Technical Essays for the Inexperienced Photographer* published in our volume for 1887 caused such a run on the JOURNAL as to have placed it out of print. During the brief period that has elapsed since then so many new readers have been added to the previous large number, and so many advances have been made in the practice of the art, that a second and much more comprehensive series of lessons has been considered desirable, and one which, in accordance with the wishes of many readers, both young and more advanced, will embrace everything of a practical nature known in the art, including the departments of manipulation, chemistry, optics, stereoscopy, enlarging, artistic composition, retouching, engraving, &c. In brief, nothing will be omitted that will conduce to imparting to the careful reader the whole knowledge of the art.—Ed.]

CHAPTER I. APPARATUS.—CAMERAS.

In the selection of apparatus everything depends upon what intention is entertained with regard to the application of the art. It is very evident that the apparatus which would be best adapted for taking portraits in either a properly constructed studio or a garden will not necessarily be that most conducive to the tourist or traveller

in foreign lands, whose *impedimenta* must be of the most condensed nature, and whose desire is confined to the securing of transcripts of such scenes as will prove mementoes of his travels. Therefore, in selecting apparatus, it is well to do so with main reference to the object in view.

For the tourist the size of camera should by preference be small and as light as is consistent with rigidity. Happily there are many such now manufactured, so many indeed as to create a difficulty in making a selection. The quarter-plate ($4\frac{1}{4} \times 3\frac{1}{4}$), as regards size, possesses the advantage of lightness, while not too small to yield little complete pictures suited for lantern transparencies, albums, or for book illustration without subsequent enlarging, although, when sharply focussed, they bear being enlarged to the extent of two or three diameters—that is, to 9×12 inches approximately—without any serious falling off in detail or sharpness.

Another advantage lies in this size of plate; they are to be had almost everywhere—the quarter-plate, being one of our best recognised standards, is kept in large quantities by every dealer everywhere. If only one lens is to be carried, one having a focus of six inches will prove most suitable for the majority of subjects; but there is a great advantage in having two lenses, one of five and the other of eight inches focus. The reason for this will be more fully dilated on when we come to speak in a subsequent chapter on photographic perspective. A camera for 5×4 inch plates possesses, for some purposes, advantages over that for quarter-plates, mainly so for facilitating book illustration and for albums, this being in virtue of their slightly increased dimensions; but this size is not so universally procurable as the quarter-plate.

The tourist's camera should have dark slides enough to enable a day's work to be done without the necessity being experienced of seeking cover to replenish the dark slides. One may go a whole day without seeing more than two subjects worth photographing; but then, on the other hand, over a dozen desirable subjects may present themselves, and for these one should always be prepared. It is not desirable, therefore, to enter upon each day's career with less than one dozen plates, placed either in double dark slides or in one of the changing boxes now easily procurable. It is necessary, likewise, that the lens be fitted with an instantaneous shutter, for although it is not wise or expedient that it should be employed in season and out of season, yet do occasions frequently arise in which the whole value of the scene lies in its having to be secured by a momentary exposure. In this it is undoubtedly "well to have a giant's power," although it would be unwise to be always making use of it.

For those who desire to make photography a pastime for the morning, or for the Saturday or other holiday, a camera of dimensions larger than in the case of the tourist may be indulged in with advantage. The half-plate camera may here be most usefully employed; and, as in the former case, it is desirable to have two lenses, one being of much longer focus than the other. The possessor of a half-plate camera ought on no account to omit a pair of stereoscopic lenses from his outfit, this class of camera lending itself so well to the production of binocular pictures. Also arrangements ought to be made by which the plate may be exposed in either the horizontal or vertical direction, to suit the nature of the subject that is to be taken. For the special class for whom we recommend this camera three double dark slides ought to be included in the outfit.

For portrait photography portability in the camera is quite immaterial. Indeed, to any except a professional portraitist a portrait camera, pure and simple, is scarcely to be recommended, as a firm, rigid, portable camera serves both purposes of landscapes and portraits. Lenses of the essentially portrait class are not necessary, unless for those who have to operate under cover, or where the light is so weak as would necessitate an otherwise protracted exposure—a thing inimical to the obtaining of a favourable expression.

It is not at all probable that leakages of light will be found in any new camera, still it is well to test each one for it previous to accepting it finally. To do this cap the lens, expand the camera to its fullest extent, remove the ground-glass screen, and throw over the head a dark cloth in such a way that it shall permit of a proper examination of the whole interior. This examination must be conducted in bright daylight, and under such circumstances as to allow no portion of the body of the camera being covered by the dark cloth. If there is the

lightest chink of light visible, either through an abraded corner of the bellows, or through an imperfectly filled screw-hole about the flange of the lens, steps must be taken to have it stopped. The consequence of inattention to this will be a fogging of the image, or a faint duplication of the subject in the negative. No light whatever must be allowed access to the camera except that which passes through the lens.

Little need be said concerning the camera stand except this, that rigidity must be possessed by it at whatever expense. Portability is a good thing, but rigidity is far better. It is possible to have both combined, and for most purposes, especially for the tourist, this combination is best.

Our Portrait Gallery.

II.—A. L. HENDERSON.

THE subject of our sketch this week is so well known, in metropolitan circles at any rate, as to render our giving a portrait of him of limited utility to London readers, to whom no better man is known as an active living photographer than Mr. A. L. Henderson. Mr. Henderson commenced his scientific career in very early life, to which the fact of his father being a medical practitioner at Edinburgh lent every facility. His early history may be summed up in a few words. Born in Edinburgh, 1833, he was at an early age apprenticed to a dentist and druggist. He afterwards became connected with the Ordnance Survey, and was one of those who were balloted out on the order being received to reduce that staff. At the age of nineteen he turned his face southwards and came to London, and became dispenser to a surgeon in Hishopsgate.

Having for some years previous to leaving Scotland studied photography as an amateur, he resolved to turn his knowledge of the art to practical account, and for that purpose he, in 1853, forsook the dispensing of medicinal compounds and adopted photography as a profession, taking for this purpose the premises in King William-street, which he occupied for so many years with such financially successful results. Here he continued until the close of his career as a professional photographer, this termination to his professional labours having been hastened by illness, he having to take a voyage to Australia to recuperate. On this voyage he set out on the 5th of last month. The large number of friends, photographic and otherwise, who attended him to the port of embarkation attests the popularity which he enjoyed up to the last.

It is needless to say that Mr. Henderson possesses an excellent and full knowledge of photography in its technical bearings. His perseverance in any department in which his sympathies are strongly enlisted is certainly astonishing. As an illustration of this, we well remember how on one occasion we, along with him, were examining some ceramic photographs which had been burnt in on enamel plaques. Our friend found fault with one, and on our somewhat taunting rejoinder that it was better than he would ever achieve, he asserted that he would beat it after a week's trial, although he had not up to that moment ever made any attempt, or had any intention of trying ceramic work. Sure enough, within the week he called and showed us several really high-class ceramics he had on that and the previous day executed. The great success he achieved in vitrified enamels soon led to Mr. Henderson's being appointed photo-enameller to the Queen, for whom he has done much work.

He was, and still remains, a member of several photographic associations, and is ever ready to contribute freely of his great knowledge and experience. Of a manner somewhat brusque, he has a warm heart and a ready hand to help, as many of his less fortunate brethren are aware.

Our portrait is from a negative by Mr. John Stuart, of Glasgow.

LIGHTING THE SITTER.

II.

IN the previous article we have considered the side walls of the studio from the floor up to about eight feet above; this space we have made of a dark or neutral tint, with adjustable white blinds to act as reflectors. In a small studio the eight feet may be reduced to seven. This height has been selected because it is usually sufficient to cut off injurious reflections from the eyes of the sitter, as light coming from above cannot be reflected into the camera from the centre of the eye, unless the sight is directed upwards, which is an unusual position.

In studios where there is a single sloping skylight, the wall opposite the casement is of a considerable height, and there is a wide space above the line drawn on it horizontally seven or eight feet from the floor. This space may advantageously be papered or painted with a white or very light tint, to act as a reflector. The space above the background may also be made light, so as to give an all-round illumination from above, which will be very beneficial in softening wrinkles and giving a lighting devoid of harshness; in some cases it will prove sufficient to light up the shadows, so that the adjustable reflectors will not be needed.

The ceiling of the studio should also be white, and the rafters or astragals of the skylight may be similarly painted, the rule being to get as much diffused reflected light from above as possible. The size of the skylight is regulated by the dimensions of the studio; it is better to have it too large than too small, so far as the lighting is concerned, as it is always possible to modify and reduce the light by the use of curtains. On the other hand, a large skylight makes the studio too hot in summer and too cold in winter, and it is frequently a nuisance in wet weather, as leakage is more likely to occur than when a small skylight is adopted.

Strong top light coming from above and behind the sitter is apt to cause dark shadows on the cheeks, making them appear hollow and thin; the eyes are also in shadow, and look deeply set under overhanging eyebrows. Hence it is no use having glass directly over or behind the sitter.

It is found by experience that the best position for the skylight to commence is several feet in front of the background. In a studio having an average height of nine feet the distance may be three feet; with a higher skylight, fifteen feet from the floor, the blank space may be increased to five feet. The skylight may extend from the top of the casement or side light far enough to cover two-thirds of the studio floor. Thus, in a room twelve feet across the skylight may be eight feet

wide if the slope is gentle, but with a steep slope the width may be increased to ten feet, in order to cover the same floor space. The length of the skylight depends also upon the height of the studio. A good rule is to make the length of the skylight the same as the height of the middle of the glass space above the floor; thus, if the roof is eight feet above the floor on the casement side, and twelve feet on the opposite side, the average height is ten feet, and the skylight may accordingly be made ten feet long.

In a double-ended studio, where a background is placed at both ends, there will be two skylights needed, which must be reckoned separately. Probably it will be found that these overlap or come close together so as to form one large skylight. With such a top window, adjustable curtains will have to be used so that the superfluous front light is prevented from reaching the sitter. Too much front light causes the features to look flat, and there is a want of relief, of modelling, and of shadow in the photograph. The casement or side light may be made of the same length as the skylight, and it should reach to within two or three feet from the floor.

Having now settled the question of size of the windows, we come to the glazing. If the photographer sits down before the background in the place where the sitter will be, he will see at once if there is any obstruction to the light. If he can see nothing but sky through the top light he cannot do better than have it glazed with clear sheet glass. If there should be a building or other obstruction which cuts

off some of the sky which would otherwise be seen, then it will be advisable to use clear glass to cover that part of the window through which he can see the sky, and for the remainder to use ground or ribbed glass, fixed with the rough surface downwards. If the ground surface were put outwards it would soon become loaded with dirt; on the inside it rarely requires cleaning. If ribbed or fluted glass is used on the low end of the skylight, that is, above the casement, the ribs should run horizontally, and not be on the slope: but if they are used on the high end, then the ribs should run on the slope. The safest way is to put a trial piece of ground glass and another of ribbed in various positions on the skylight, and see which gives the most light from the sitter's point of view. When the skylight is glazed, it is evident that the sitter will be able to see clearly all the sky available through the clear glass, but he will not see the light-obstructing buildings on account of the ground glass intervening. The same system can be employed with the side light. If the sitter can see the sky through the upper part, then this part should be glazed with clear glass: below this, ground or ribbed glass, with the ribs running horizontally, is preferable.

Frequently the side light is rendered almost useless by surrounding walls, trees, or buildings. In such a case great benefit is obtainable by the use of long narrow mirrors, framed so that the rain-water will drain off the front of the mirrors without reaching the back.

These mirrors may be fixed outside the casement and arranged like the bars of a venetian blind which has been hung askew, that is, with one end much higher than the other, the glass being about six inches wide and four inches apart, and placed at an angle of forty-five degrees from the horizontal. They may be permanently fixed so as to reflect as much skylight as possible on to the sitter. The commonest quality of thin silvered glass, or of patent plate, is better for this purpose than the ordinary thick plate-glass mirrors. A projecting board, two feet wide, placed outside, at the top of the casement, will prevent a good deal of rain and dirt settling on the mirrors; this board should be placed so that only its edge can be seen from the sitter's position.

A casement filled with mirrors in this manner will give almost as much light as the skylight. When persons with sunken cheeks or overhanging eyebrows have to be photographed, it will often be found that the most pleasing portrait is a full front view, with the skylight completely covered with curtains and the illumination derived solely from the side light, the shadows being softened by the free use of the reflecting blinds. With this device a surprising appearance of plumpness may be imparted to a thin face. On the other hand, with a person whose eyes stand out prominently so that the eyebrows scarcely overhang at all, we may screen off the side light and front light altogether, and let the illumination be from the skylight above the sitter. A shadow may in this way be thrown over the eyes, and a pleasing portrait secured.

From these examples it will be seen that curtains or blinds should be provided for both skylight and casement, so that every foot of the glass can be covered when required. Dark green blinds with spring rollers are the best; they should be arranged so that a slight pull on a cord will cause them to roll and unroll at pleasure. The rollers should be fixed to the upper end of the skylight, the blinds being about four feet wide, and overlapping slightly to prevent light reaching the sitter from the space between the blinds. The coiled springs in the rollers will suffice to keep them tight, so that one cord to each will be sufficient, the cord passing through a ring or screw-eye at the top of the casement, and fixed by a turn or two round a little belaying pin on the studio wall.

ALBERT W. SCOTT.

ECHOES.

Two or three weeks ago I referred to the alleged difficulty experienced by dwellers in towns in obtaining cloud negatives owing to the angle at which they would be compelled to tilt the camera, and pointed out that such difficulties were apparently exaggerated. In last week's issue I see my fellow-contributor, "Free Lance," also alludes to the

matter as having had more made of it than necessary, but I am afraid his remarks may be read by some so as to mislead in a contrary direction.

His argument that very few pictures including clouds exhibit the latter right down to the horizon line is all right so far, but when he goes further and implies that, therefore, a town dweller may from an "attic window" meet all the requirements of cloud negatives for general purposes, I fancy most of those who have tried it will be inclined to dissent from him.

If the attic window artist merely wished to introduce clouds into a photographic transcript of the terrestrial scene before him, of course he could scarcely have a better point of view from which to do it, and the same negative would answer equally well perhaps for any such subjects whose sky outlines suited it. There lies the point. I said (April 12) "what is wanted is a tolerably unbroken horizon;" it is surprising how small a projection, in the shape of a chimney stack or tree top, will entirely spoil for use an otherwise good cloud negative. The fact is, the first few degrees above the "skyline" comprise the really "business portion" of the sky negative, and if these are spoiled by unseemly projections there is little left that is of use. I have seen a series of cloud negatives taken from an upper window and looking right out to sea, in which of course the clouds

reached down to a very low horizon, but they were utterly useless, because, unnoticed when they were taken, a signal pole or beacon of some kind projected upwards into the sky in the very centre of the field of view, and so rendered all the low-lying clouds unavailable for use.

I repeat, then, that a straight skyline is a *sine quâ non*, whether the point of view be an attic window or *terra firma*. Of course, in a situation surrounded by buildings or trees the attic window elevation becomes a valuable, if not indispensable aid, but out in "the open" it is quite needless.

Mr. R. H. Bow's method of binding lantern transparencies, in which the mat and separate binding strips are replaced by a single folding mat, is a very good one when the mats are properly cut and exactly suited to the thickness of the glasses; but if this be not the case endless trouble will be the result. It was very likely from Mr. Bow's description of this method a quarter of a century ago that I was myself induced to try it, but after doing my best in the way of cutting

the masks, I returned to the old way as being better and far less trouble. A friend of mine some few years back had a number of such masks cut for him by a professional maker, and though they cost him as much, or more, *per dozen* than the ordinary masks and strips *per gross*, he eventually put them from him and used the latter.

I have often wondered that no such instrument as the diaphoscope, also described in last issue by Mr. Bow, has been previously put forward commercially for the same purpose. Nowadays nearly every photographer possesses a lantern with the necessary stock of slides, and these form, independently of the lantern, quite as interesting pictures as those on paper. They are small it is true, and in order to see them properly, it is, under ordinary circumstances, needful to crane the neck at an uncomfortable angle in order to get them against the light. Even then a piece of ground or opal glass is necessary before they can be properly examined, for the lay individual is not usually up to the wrinkle of viewing transparencies by light reflected from a sheet of paper or other material. Hence, when the lantern itself cannot be brought out, its slides remain in their boxes, and much pleasure is thus lost to the world. With the diaphoscope, however, we have a new power, which we may place second to the stereoscope and far ahead of the graphoscope.

It has been the fashion for some years past now to look back upon the "good old collodion days" and to regard the "wet plate character" as the standard of excellence to be aimed at in our modern work. I do not know whether modern results are improving or ideas changing, but certainly I was startled somewhat in last issue to find some gelatine negatives described as of the "collodion type," as if that were something inferior.

Thus the Rev. W. Miles Barnes describes how he had exhibited to a French photographer some of his pyro-developed negatives, which the professional acknowledged to be superior in delicacy and gradation and all that to his own, which were developed with ferrous oxalate. These latter are described by the writer as having some of the finer details obliterated by the piling up of the lights while the pyro-developed films were in perfect gradation. The French artist's inferior negatives are finally described as having "the qualities and very much the appearance of good negatives of the old collodion type." Surely but a short time ago no higher praise could have been given to a gelatine plate.

By the death of Mr. Warren de la Rue we have lost one of the "old hands" in photography, one perhaps but little known to the present generation, at least among photographers, although he was one of the very earliest to successfully utilise the science in the wider field of astronomy. I am afraid to say how many years it is since I first admired his wonderful lunar photographs, especially those in stereoscopic form, showing in strong relief, not only the spherical shape of the moon's body, but also the hills, valleys, and craters on its surface. This result was obtained by taking the two dissimilar pictures at intervals of several hours, which, owing to the moon's motion during the time, was equivalent to taking them from points of view some thousands of miles apart.

Mr. De la Rue was like the late Professor Spottiswoode, a wonderful example of the English business man and scientist combined. Both of them while actively directing large commercial concerns found time to devote to scientific pursuits to such good purpose that both were Presidents of leading societies—Spottiswoode of the Royal Society, and De la Rue of the Royal Institution, the Chemical Society, and the London Institution, proofs that they were something more than the "mere amateurs" it is too frequently the fashion to deem such men.

JUNIA.

AN EASY AND ECONOMICAL METHOD OF MAKING LANTERN PLATES.

No. III.—THE DRYING BOX.

IN the preparation of gelatine dry plates the first thing required to be done is to make arrangements for the drying of the plates after they have been coated. To do this a drying box or cupboard will be necessary. This consists of a light-tight chamber, through which is passed a rapid current of air.

I think the easiest and most satisfactory way of doing this, for any one preparing plates on a small scale, is to cover up a fireplace and let the drying box containing the plates stand in front of it with its outlet for air connected with the chimney, by this means a rapid and constant change of air is obtained through the box.

My own drying chamber consists of a large box with a light-tight door, with an inlet for air near the bottom and an outlet at the top passing through the boards in front of the fireplace to the chimney.

For temporary use a large sheet of strawboard or brown paper fastened over the front of the fireplace will do as well as the boards.

The plates are laid face upwards on a series of shelves, and the current of air obtained by the draught in the chimney passes over each in turn, as shown in the above diagram.

This is a very good arrangement if one has plenty of room or only requires to dry a few plates, but if I had to make another drying box I would use racks to stand the plates in instead of laying them on shelves, and thus save space; and instead of having a door I would have a lid and put the racks into the box at the top.

There are many forms of plate racks, but I think the best for this purpose (because the film is not liable to get injured) is a strip of wood $14 \times 3\frac{1}{2} \times \frac{1}{2}$ inches, with twenty-six little wooden quarter-inch pegs about three inches long stuck in it two abreast and one inch apart thus—

The plates stand in the rack thus, face upwards.

If we purpose coating half a gross of plates at the time, we shall require six of these racks, which will do for larger sized plates as well, and are very useful for drying negatives in, as they do not rub up the film.

The drying box will require to be large enough to hold the racks without crowding them close together. In the lumber room of most households a suitable box might be found if some brown paper be glued over the joints to make them light tight.

A A are a row of holes at each end of box, about three inches from the bottom.

B, inlet for air.

C, outlet for air with tube connected to chimney.

D D, a strip of indiarubber draught excluder similar to that used for doors, or a piece of indiarubber tubing fastened round the edge of the box by a strip of black twill glued to each side of the wood thus—

E, the lid; this can be fastened down by hooks or a weight placed on the top, which would press down the tubing sufficiently to make it light tight.

F F are strips of wood fastened to the ends of the box to form a passage for the air and at the same time blocking out the light. The air space in the outlet requires to be rather larger than the inlet. Paint them black before fixing them to ends of the box.

If the lid of the box fits well, instead of the indiarubber tubing a strip of (double thickness) black twill eighteen inches wide glued all round the outside of the box about two inches from the top and then folded over the lid would keep the light out all tight.

Indeed, with a little ingenuity one can find various methods of making a small drying box. It will also be found very handy for drying negatives in after they have been fixed and washed, instead of having to leave them standing about in the racks to dry.

HERBERT S. STARNES.

GROUND GLASS SENSITIVE PLATES.

WITH the view of giving a further helping hand to the use of obscured or ground glass as a support for the sensitive emulsion, I wish to state that twenty years ago it was found, in decorating embossed glass, that a finer surface could be got by adding chloride of ammonia to the usual fluoric acid. This acid is bought in druggists' shops and sold in lump. As it is gradually added to the fluoric acid, the effect is to change the obscured portions to one of whiteness and less transparency. Hence it has become known as "white acid."

Glass, thoroughly cleaned (and kept from finger-marks), when placed for two minutes in the gutta-percha tray becomes white and opaque, very fine in texture, suited in a high degree for the retoucher's pencil; besides this, the emulsion adheres more firmly to the glass,

also increases the sensitiveness by the greater quantity of emulsion it holds, and is consequently freer from "frilling."

I see no reason why this process should add greatly to the cost in producing sensitive plates, when you consider its non-halative quality added to those I have already stated. JAS. ALEX. FORREST.

THE ART OF RETOUCHING.

[A Communication to the Birkenhead Society.]

THE value of retouching as an aid to the practice of photographic portraiture is now so universally recognised, that no effort of mine is needed in order to prove its practical utility.

The term retouching is somewhat a misnomer. It implies the *continuation* of some process or method of touching, which really is not the case. The words "photo modelling" would, I think, be far more suggestive and helpful to the uninitiated.

The object of retouching cannot be too clearly stated. It is not to make poor negatives good (though to a certain extent it will do this), it is rather to make good negatives perfect. Under-exposed or over-exposed negatives will always give unsatisfactory results even though they be worked on by a skilful retoucher. What is really needed is that portraits shall be well lighted, well timed in exposure, carefully developed, and judiciously retouched. The result will then be perfect.

I have hinted that it is almost impossible to get a truthful and pleasing portrait by purely photographic means. Unfortunately the art does not lend itself to the re-production of colour, a fact which accounts for many blemishes in the photographic negative. For instance, fair-complexioned people with ruddy faces have a tendency to photograph dark; other light-coloured skins are covered with freckles, which, being yellow in colours are invariably reproduced as so many black spots; temporary pimple, and blotches are reproduced in like manner; whilst wrinkles and facial lines are often so exaggerated as to appear most objectionable.

All these defects may be completely removed by the judicious use of a sharp pointed lead pencil. The transparent parts of a negative which indicate the ruddy cheeks of a fresh complexion may be filled up by carefully interweaving pencil lines until it is brought into harmony with the surrounding parts. Freckles, pimples, and blotches may be obliterated by light touches, and wrinkles and lines may be softened in like manner. This part of the work is generally known as "smoothing" the face, and is the least important part of the retoucher's work. That which exercises his skill in a far greater degree, and which requires more than ordinary amount of artistic knowledge, is what is called "modelling the face," by which means the high light, half tones, and deeper shadows are brought into harmony the one with the other, making the resulting portrait pleasing and effective, and in accordance with the artistic laws that govern light and shade. To do this effectually requires a close examination of the portrait negative previous to commencing operations. Should the high lights appear flat, it will be necessary to build them up with pencil until a natural effect is produced. A corresponding amount of attention must also be paid to half tones and shadows, the former being treated most delicately at all times.

The principal lights are the top of the forehead, over the eyebrows, the bridge of the nose, and the cheek-bone. The middle tints and deep shadows are indicated in every negative, and consequently do not need description.

The value of retouching in connexion with expression in photographic portraiture cannot be over estimated. It very frequently happens that a cross look is caused by knitting the brow, which produces lines between the eyes. The softening of these lines by retouching almost invariably produces a result that, compared with a print from the same negative before being so dealt with, is simply marvellous. Again, the lines of the mouth when drawn down very often causes a sarcastic expression, or if drawn up produces a grin; but, if these be carefully softened down by retouching, pictures which would otherwise be considered valueless will be carefully treasured as pleasing and truthful portraits.

The novice in the art will naturally desire to produce such results with as little delay as possible, and it most frequently happens that beginners endeavour to fill up *all* the lines in the face with a view of producing a clean, marbly effect, which, through want of knowledge, they consider the highest flight of the retouching art. A greater mistake could not be made. In no instance should the individuality of any portrait be lost. Perhaps this phase of our subject is the most important, for what *not* to do is even of greater moment than *what* to do in the endeavour to produce a faithful portrait. For instance, if the lines in an aged person's face were filled up, it would probably make them appear young, and only the

outline of the face would be recognisable; or, again, if the hollow cheeks of a thin-faced person were so worked on as to produce the effect of one in full flesh—as a portrait such a picture would be worthless. It cannot, therefore, be too strongly urged that in every retouching effort nothing should be done that will in any way interfere with the production of a truthful portrait. Tone down exaggerated lines, take away altogether such blemishes as are not permanent, build up the lights, and improve in every respect where faults are due to defective photography, but in no case endeavour to make the old look young, or the ugly pretty; for however much we may flatter ourselves or seek to flatter others, the truth is strong, and in the long run must prevail. W. WILKINSON.

COPYING PAINTINGS AND WORKS OF ART.

I.

THIS province of photographic work is one requiring training, aptitude, and attention; being rather out of the ordinary routine of the professional portraitist or landscape amateur, perhaps a few notes from a thirty-year record of work in this special direction may prove of some value, and be an addition to the knowledge of many of the readers of this JOURNAL in this, which is probably the most difficult problem in applied photography, with the exception of astronomical and microscopic work, if they may be excepted.

There is an essential difference necessary in the treatment of old and new, or rather ancient and modern, works of the painter's art, and the first-mentioned will receive the earlier notice. All old paintings that have passed through my hands in the course of a long experience as a cleaner, liner, restorer, and dealer in pictures, may be put down as having been at least once if not many times varnished, and this no matter on what they may have been painted—wood, canvas, metal, or other material—or which grounds they may have been painted on, or, on the other hand, in what medium they may have been executed. After having been varnished they are practically oil paintings, and through their protective coatings of varnish or other covering, they become amenable to the same treatment on being photographed. Such pictures, no matter on what ground they are painted, or on what material, after a life of, say, a hundred years, become more or less cracked all over, some of them more, some less; perhaps the most perfect I have seen having been small panel pictures painted by the reputed inventors of oil painting, the brothers Van Eyck—in the fourteenth century I think, without looking up the exact date. In photographing such pictures, which are generally to be found in collections, public or private, it may easily be understood that unless under special circumstances they must be photographed as they are, with all their faults and imperfections, as many of the foreign collections have been, thus affording not only the means of seeing them as they are, and the state of decay or preservation they may be in, but securing for posterity a record of their condition at the time the photograph was taken. In this connexion it may be mentioned that the collections of two members of the present administration have passed through my hands, I hope skilfully and think successfully. In both cases the pictures were photographed before being touched, and again after finishing, so that the most careful examination could be made and comparison instituted. This, more especially in the case of family portraits, is a most important matter, for no one would like to see or know of the similitudes of historical celebrities being injured or altered in any way.

In both cases an interleaved photographic catalogue (royal quarto-sized paper, the photographs differing but the sizes of all being recorded) was made of the collections for present use and future reference; and that this was necessary will be seen from the fact that in one of the cases there were two MS. catalogues of the collection of different dates, the earliest being over a hundred years old, and even with their aid, in many instances, there was very great difficulty in identifying many of the pictures which had been unmarked or had had the markings removed, some even lost altogether, others their places changed in the mansions, and other causes, a thing which need not again occur. The idea is made a present of to the profession, and ought to be of great value, as I believe that at the time it was initiated it was so for the first time, at least in a private collection, if not in a public as well.

The place where to photograph a picture is always a difficult thing to decide upon, to get the best light for the work, as old pictures may be put down as a rule to be very non-actinic, partly from the darkening of the colour and partly from the yellowing caused by oxidation of the varnishes and the gradual accumulation of what can only be called *dirt*, no matter how carefully a collection may be looked after; indeed, it is the worst thing for pictures to be constantly dusting, washing, and

wiping them, the continual doing so resulting in almost irreparable injury to many of them.

Most people are aware how readily polished mirror plates become first clouded, then tarnished, and ultimately obscured, in the cleanest of households, on the surface of the plates. This form of dirt is generally produced by the combined action of the decomposed products of artificial lighting and heating, the exhalations from the person, from the atoms floating in the atmosphere, and so on, and is made plainly visible on the polished mirror plate; but the same action and effect is taking place on the surface of every picture or other work of art. And, in addition, if the picture is painted on canvas, almost every time a window or door is opened and shut, especially if rapidly or violently, the canvas is shaken more or less on its stretcher and in its frame, and the colour and the ground on which it is painted becomes in time more or less cracked—first round the framework of the stretcher, and ultimately all over the picture, this being but the mechanical action, and is quite apart from the action of the paint itself and the varnishes used, which dry at different rates of speed, so to speak, the quicker drying contracting and rending the slower, till in some cases we have a perfect network of cracks, which become receptacles for all kinds of dirt, this being accompanied by the invariable relations of age—decay and destruction.

If such a picture must be photographed, say, in the "country," to save removal, or because the proprietor has objections to its removal to the studio, then the best method I have found in practice is to do it in the open air, and in the sunlight if possible, so placing the picture that the angles of incidence and refraction shall be such as to cause no useless reflections on the plate. This may be best arrived at by placing the picture opposite the sun, with grass or something dark below—a large black cloth being the best—and the camera with its back to the sun. I would on no account coat such a picture as is alluded to with any substance whatever, trusting rather to the full action of the light and long exposure to it; indeed, in the case of old pictures it is almost impossible to over expose them, and as I am now writing of the collodion times and practice, long exposures required special preparation of the materials used, a topic which will be treated of further on.

With the full liberty and permission of the proprietor of such pictures, I have, in order to get the best possible results, washed, as we call it, but what is really only damp-rubbing with a washleather or soft cloth, and polishing with an old silk handkerchief, after careful dusting, but on no account should soap be used. This, with any after treatment of what can only be described as temporary varnishes, I never trusted, and would not, in the hands of the ordinary photographic operator, who, whatever his photographic skill, can hardly be supposed to know much of the handling and treatment of valuable pictures. In such hands they are best left alone, but in the hands of, and under the supervision of, a person skilled in and accustomed to the treatment of such pictures it is quite a different matter.

Reverting to the "mirror" illustration given above, I have found in practice that the peculiar deposit is most easily removed by a very harmless material, namely, common white vinegar and water, or, what is practically the same thing, a few drops of acetic acid put into a tumbler of water; the thick tarry scum is quickly removed if the cloth be damped with this, and no harm accrues to the vitreous surface, which is afterwards finished with a cloth or washleather. Applying this idea to the varnished surface of pictures, I have found that much of the superficial dirt acquired in the same way has been most successfully removed without the slightest injury to the picture by the same treatment carefully carried out. Of course, the weak acid is not to be slushed on or allowed to soak through the cracks (if any), but lightly and skilfully done, and with "common sense."

If further cleaning up of the picture be needed, almost any of the methods suggested suit the purpose if carefully done. I believe I have used them all, from strong brown stout, through all varieties of syrups and water, or rather syrup thinned down sufficiently to become for the time a temporary varnish; but I have found that in summer-time if there are any or many flies about they are sure to be attracted by the scent presumed to the surface of the picture during protracted exposures. Glycerine has not this disadvantage—at least, in the same degree; and if a watery solution be used, or desired to be used, it will be found the best in practice when reduced to the proper consistency.

Some of the oils, where such a liberty can be taken, may be used with great advantage to the clearness and clearing up of shadows and dull portions of the picture, and bring the whole to a uniformity of surface more fitted for photographing; some of the oils only however, and those not of the drying kind, such as linseed for instance, or any of that class, but rather those which do not readily dry, such as lard, or sperm of the animal oils, and olive of the vegetable. Castor is too viscous for use.

All of these, however, must be most carefully removed, and in the case of severely cracked works it will be found extremely difficult to do so, although the remaining of an infinitesimal film may—indeed, can—do no possible harm, and on the whole they are safer and better than the watery temporary varnishes.

W. H. DAVIES.

LORD RAYLEIGH ON EXPERIMENTAL OPTICS.

VII.

In his seventh lecture at the Royal Institution upon the above subject, Lord Rayleigh said that diffraction phenomena can be produced without ruled lines, for almost any irregularity will produce the effect, and Brewster showed that the property can be transferred from one substance to another. If a solution of gelatine be poured over a glass diffraction grating, then allowed to dry, and afterwards be stripped from the glass, it will act quite well, and produce the main effects of the original grating; but good optical definition out of such a grating cannot be expected, because the surface is not flat, and some force is required to pull the gelatine film from the glass.

Another method of reproducing a grating is to throw down a thin film of pure metallic silver by reduction from a silvering solution upon the face of a glass grating; this very thin film will act as a conductor of electricity, so can be thickened by electroplating it with copper until it is strong enough to be self-supporting, and then it can be separated from the glass.

A method of making gratings, which he had himself introduced, was to multiply an original by means of photography. It has to be reproduced about the same size as the original, and no microscopic or other lens can be expected to give a sufficiently perfect image for the purpose—it is not in the nature of a lens that it should do so; but by laying the original grating upon a truly flat sensitive plate, and throwing a shadow of the lines upon that plate, it is perfectly possible to get very fine gratings, giving spectra quite comparable with those produced by the original. Lord Rayleigh did not say whether he used collodion or gelatine dry plates, or Daguerreotype plates. With gelatine dry plates especially, the question would arise as to the influence of different sizes of the solid particles in emulsions of different make.

The lecturer then said that the lines for the production of diffraction phenomena need not necessarily be straight. In years gone by, Barton discovered that if numerous fine lines were drawn by a diamond point upon steel, and the steel were subsequently hardened, the block thus prepared could be used as a die to reproduce the lines upon silver or other metal. In this way "Barton's buttons" were made; in sunlight or gas-light they glittered and gave a display of colours, something like those given by the diamond and other precious stones. He here placed a Barton's button in the path of the beam from the electric lamp, and its reflected image upon the screen displayed the colours of the spectrum in a complex image of elegant symmetrical form.

Lord Rayleigh said that the way in which Professor Rowlands manufactures the original gratings is a triumph of mechanical skill; in the intervals between the lines there is not a difference amounting to $\frac{1}{1000}$ part, and perhaps to not $\frac{1}{10000}$ part.

Diffraction may be produced by means of seeds, but the seeds or other particles must be pretty nearly of the same size. He here produced rings of colour by placing a piece of glass dusted with lycopodium in a narrow beam from the electric lamp, which was throwing a small spot of light upon the screen; a coloured halo upon the screen was the result. He said that these coloured rings are not the same as Newton's rings. On the same principle those halos are produced which are seen round the sun and moon in certain states of the weather, and it is possible from the size of the rings to calculate the dimensions of the particles which produce them, because halos of this class always signify that the particles producing them are nearly of the same size.

Lord Rayleigh then threw a small bright disc of polarised light upon the screen by means of the great Iceland spar prisms presented to the Royal Institution by the late Mr. Spottiswoode. In the path of the light he placed a vessel with glass ends filled with bisulphide of carbon, and surrounded by a coil of insulated copper wire. Whenever the current was sent through the coil, the bisulphide of carbon rotated the plane of polarisation, and rotated the blue rays more than the red; this fact was first discovered by Faraday, and in that place. When light passes through a solution of sugar the plane of polarisation is also rotated, and on this principle the saccharometer is made. By its use brewers, sugar-refiners, and others can tell how much sugar there is in any particular liquid, whatever other substances may be present. He (Lord Rayleigh) had utilised the phenomenon just described as presented by bisulphide of carbon, in the devising of an optical instrument for measuring electrical force.

Why is the sky blue? Brewster supposed the colour to be due to thin plates, as in the soap bubble, for it was once thought that all the particles of water floating in the atmosphere and forming mist or cloud were small, hollow bubbles. The blue of the first order produced by thin plates is, however, very faint, and not the rich blue of the sky; there is also no evidence that the particles of water floating in the atmosphere are hollow. It seems probable that the blue colour of the sky is due to floating seeds,

for minute germs are everywhere, also to other small floating particles of organic and inorganic matter. The light from the sky is polarised, and by pouring a solution of gum mastic in alcohol into water, a turbid mixture results which exhibits a bluish colour and a polarisation not unlike that of the blue sky. Professor Tyndall had proved in that theatre that violet light would precipitate certain vapours into clouds, which at their formation looked blue, and that their polarisation was not unlike that of the sky. The earth is not alone lighted by the direct rays of the sun, but to no inconsiderable extent by the light reflected from floating particles in the atmosphere, also by light scattered by the earth. The polarisation of the light from the sky can be seen on examining it with a Nicol's prism; observers standing upon mountains in a pure atmosphere see the polarisation more strongly. The problem of the blue colour is easier to explain than the polarisation, for if floating particles be present, comparable in dimensions with the wave-lengths of light, then the smaller particles might be expected to act upon the shorter waves more powerfully than upon the longer ones. The speaker here placed a solution of common hyposulphite of soda in a rectangular glass vessel in the path of a parallel cylindrical beam from the electric lamp, and added to it an exceedingly weak solution of some acid, so that a minute or two elapsed before any sulphur began to precipitate and to render the liquid turbid. When the particles first began to form, the liquid looked bluish, and the light passing through the trough and forming an illuminated disc on the screen became light yellow; in time the yellow deepened to orange and the orange to red, as with the setting sun. Lord Rayleigh said that in private it is best in this experiment to use acid so weak that five minutes elapse before the liquid begins to become perceptibly turbid; but so much time cannot well be occupied over it in a public lecture. The precipitation can be arrested at any desired stage by adding ammonia until neutralisation is effected.

Only a few weeks ago Professor Hartley discovered that ozone has a blue colour if you only look through a sufficiently long column of it. The observation in itself is interesting enough, and Professor Hartley tried to apply it in explanation of the blue colour of the sky; but Lord Rayleigh thought that view utterly untenable, because then the sun should be blue when gazed at, and the sky away from the sun should not look blue. Professor Hartley also tries to explain the blue colour by fluorescence, which does not explain the red colour of the setting sun, although it might explain the blue of the sky. Then, again, with fluorescent light there is no polarisation, and if there is one thing we are more certain about than another, it is that the light from the sky is polarised. It seems to be certain that the blue colour of the sky is due to diffraction—to the scattering of the light by small particles.

THE GLASGOW AMATEUR PHOTOGRAPHIC EXHIBITION.

(From our Special Correspondent.)

ALTHOUGH somewhat later than usual in the date of their fixture, the Executive of the Glasgow Amateur Photographic Association are to be congratulated on the success of their sixth annual exhibition.

As was the case last year, they have wisely, we think, again used their own commodious premises, situated at 180, West Regent-street, for their annual exhibition. In one or two matters the Executive have seen fit to depart from the use and wont of the past.

Looking over the collection we find a number of well-known local amateurs conspicuous by their absence, this is specially noticeable in the case of Mr. Hugh Reid, who took first honours in the Landscape Class last year. Messrs. George Murray, W. C. Hume, I. Ovenstone, John Parker, and W. Goodwin are not represented, but their places are well filled by new aspirants for honour.

We are pleased also to notice that several of the lady members of the Association have this year sent in pictures, among whom as specially deserving notice are Miss Robertson and Miss Lang; the former lady contributes a series of pictures representing a Scotch washing, and although in point of composition they are not altogether perfect, and would have been improved had they been taken in better light, still they are very creditable productions indeed.

In point of numbers the exhibits quite fill the walls of the large suite of rooms, and taken as a whole it must be said that the exhibition is a long way ahead of that of last year.

Perhaps the poorest class is the "Instantaneous," in which Mr. Snell Anderson is represented. We have seen much better productions from this celebrated amateur's cameras; somehow his pictures are too grey in tone and are somewhat spotty. His best picture is an instantaneous view of Regent-street, London.

In the Landscape Class M. Donald Dove takes first honours. He is represented with three whole-plate pictures; they are well composed, and perfect in balance and tone, and Mr. Dove is to be congratulated on his success.

In the Interior Class we were much pleased with the excellence of Mr. David Clark's picture of the interior of a mosque at Constantinople. Mr. Clark has quite recently returned from an extensive tour in the East, and this is one of the best pictures he secured; for delicacy and detail in the fine tracery we have seldom seen anything to equal this production, and the enlargement, which also takes the place of honour in its class, is from the same negative.

In Portraiture Mr. Berger takes first place. We must, however, confess to a feeling of disappointment in the exhibits of this class. There is a want of plasticity in Mr. Berger's pictures; but, taking all into consideration, perhaps the judges could not have done better.

Mr. David Clarke is also represented in this class. His head of a Russian peasant is a very fine bit of work; but his exhibit is somewhat spoiled by a companion picture in the same frame, which he titles *On a Tree Top*. This is a picture of two ladies evidently balancing themselves on a bough, and Mr. Clark has fallen into the error of turning the eyes in the opposite direction to the head.

The prize for the most artistic picture in the exhibition has gone this year to Mr. Archibald Watson, who secures the amateur medal for his *Babes in the Wood*. Mr. Watson is to be congratulated on his success. In this class he was, however, closely followed by Mr. Oliver with another of his charming little studies, like *Waiting for a Nibble*, which secured him the place of honour last year. Mr. Watson's picture, however, is a strong one, and is original in conception. It represents his little children lying in a wood covered over with leaves—like most of Mr. Watson's pictures it is nearly perfect in balance and tone, and reflects much credit on him.

The exhibition, which was opened on the 20th instant, is free to the public, and remains open till May 4. During its continuance the Executive have arranged for a series of lantern entertainments. The first of these was given before a very large audience on Wednesday, the 24th ultimo, when Mr. James Moore, a gentleman long and favourably known in connexion with the Optical Department of Mr. James White, optician, Glasgow, took charge of the lamps and gave a most excellent entertainment. The pictures were projected on an opaque paper and cloth screen, which has been kindly presented to the Association by Mr. John Morrison, jun. This screen, which is about twelve feet square, is run up on a roller just like an ordinary window blind, and will doubtless prove a great acquisition to the members. In its way it is about the best thing of the kind we have seen, and will save a lot of bother in the future.

The next limelight entertainment is announced to take place on May 3, when Mr. Moore will again take charge of lanterns, on which occasion he will show a collection of slides sent in by members of the Association.

In the Transparency Class Mr. W. Snell Anderson takes first place, but is closely followed by Mr. Watson, who exhibits three charming little transparencies taken on Mawson's plates.

Mr. Anderson's pictures are the most artistic however, and we think the judges did right in placing him first. His slides, however, are not toned.

The Executive arranged for the awards being adjudged by two professional photographers, who were assisted by an artist. These duties were kindly undertaken by Mr. William Allan, of Ayr, and Mr. James Paton, of Greenock, while Mr. Young this year again gave the weight of his artistic knowledge in the selection of the pictures.

Altogether, the Glasgow amateurs have this year brought together a very interesting collection of photographs, which the Glasgow public are not slow to appreciate, for the rooms are daily and nightly visited by large crowds of visitors. It is contemplated to wind up a most successful winter season with a smoking concert at the close of the exhibition. The enormous success which lately attended a similar meeting of the Parent Society evidently tending to encourage such a final to a most successful amateur exhibition in Glasgow.

We append list of the prize winners:—

Class I. Landscapes: first prize, Donald Dove; second prize, Archibald Watson; third prize, Thomas Taylor. (Small size): first prize, John Morrison, jun.; second prize, John C. Hutcheson; third prize, Charles C. Coulson. **Class II. Figure Studies:** first prize, Archibald Watson; second prize, J. C. Oliver. **Class III. Instantaneous:** first prize, T. Steven, jun.; second prize, J. C. Oliver. **Class IV. Portraits:** first prize, E. James R. Berger; second prize, David R. Clark, M.A. **Class V. Groups:** first prize, J. A. Blackie. **Class VI. Animals:** first prize, James Fleming; second prize, Charles C. Coulson. **Class VII. Still Life and Interiors:** first prize, David R. Clark, M.A. **Class VIII. Enlargements:** first prize, David R. Clark, M.A.; second prize, W. Snell Anderson. **Class IX. Transparencies:** first prize, W. Snell Anderson. **Class X. Developed Prints:** first prize, David R. Clark, M.A.; second prize, Charles C. Coulson. "Amateur Photographer" Medal for most Artistic Picture: Archibald Watson.

THE CAMERA IN SWITZERLAND AND ON THE ALPS.*

If time admits, it will well repay the trouble to take the steamboat which crosses the Lake of Nèuchâtel, and passing up the canal which connects the lakes of Nèuchâtel and Morat crosses the latter lake to the little town of Morat, which is very picturesque—quite a miniature Berne. A picture might be taken of the town from the landing stage (one-half of a second, f-34), no time must be lost if the passenger arrives by the twenty minutes past three boat, as the last boat leaves at four. Walk up the hill to the main entrance, take a view of the town from the archway, go up the one street and take a view each way from the centre (one second), go out the upper end, and following the road descending towards the lake and landing-stage you will find two or three hits on the way.

At the time we were at Nèuchâtel there was a Venetian fête on the lake; the

* Continued from page 288.

numberless boats decorated with thousands of coloured lamps fitting to and fro, the reflections of these and of the coloured fires and fireworks on the lake were fairy-like.

At Berne we were induced to try a German-Swiss hotel instead of the Belle Vue, to where we were going. Two ladies entered with ourselves. On asking the proprietor for rooms, he said he regretted he was unable to give us rooms on the first and second floors, as the members of the "ballet" had engaged them all for two months. One of the ladies overheard this and surprised us by the vehemence of her language. "Good gracious!" she exclaimed; "what a dreadful place! Let us go to another hotel. The members of the ballet, indeed! and all the best rooms in the house taken up by the hussies!" She was pacified on being informed that the members of the Palais—pronounced ballet by the Germans—were not ballet girls, and had nothing to do with the theatre, but were members of the Swiss Parliament, which was then in session.

A gentleman who sat next to me at dinner informed me that at the last hotel he was staying at an absent-minded gentleman sitting near the head of the table helped himself to a glass of fish sauce from the bottle standing near him, and did not discover his mistake until he had tasted it the second time. On being asked how it was he did not discover his mistake from the flavour, he replied that he thought the peculiar flavour was due to its being the wine of the country.

It is scarcely possible to say what should be photographed in Berne, there are so many nooks and corners where pictures may be obtained, but I suppose the view from the Schanzli would be one; the old clock tower, with its performing bears, old man, fool, and cock, another; and the streets on each side of it (one second for each); the bear pit might also be taken. On our first visit to the pit two old bears were prowling around, and four young bears were disputing themselves on the shortened branches of a tree stem which had been planted in the centre of the pit. I only regretted my camera was not with me then. On the following day, when the camera was on the spot, only one bear was to be seen, and no amount of bears would tempt him to a spot where he could be photographed. At last a young man standing near came to the rescue; he plucked some grass and leaves of a tree, tied them to a string, and let the bunch down on the sunny side of the pit; the bear caught sight of it, and whilst he was walking across after it this photograph was taken on a Carbutt plate with a shutter. Had I known what was to follow I should have waited, for the young man drew up the grass, and Bruin, to catch it, reared on his hind legs and reached out head and paws after it, when a first-rate picture might have been obtained. This will give a hint to any one who proposes engaging in a similar undertaking.

Take care that you do not fall over into the bear pit, as an Englishman did many years ago, and was so warmly embraced by the bear that he died on the spot. He was less fortunate than the prisoner who found himself *tit-for-tat* with the bear, to the mutual astonishment of both. The old bear pit was formerly in the town, adjoining the wall of the prison. One night a prisoner who had been condemned to death succeeded, by means of an iron tool he had secreted, in withdrawing some stones from the wall of his cell; he was working away assiduously when he heard, as he supposed, another unfortunate prisoner assisting him from the other side; this greatly encouraged him, and he worked with redoubled energy; one huge stone resisted his utmost efforts, but at length it gave way under the more powerful strokes of the other prisoner, and the way of escape was open, but, to his surprise and horror, the other prisoner proved to be the bear, who, led by the instinct of destructiveness, hearing some one breaking down the wall on one side proceeded to do the same on the other side. What was to be done? To remain was death, to go into the bear pit might be death likewise; he determined to face the bear rather than the executioner. The bear let him escape and then made his way into the prisoner's cell, and when the jailer paid his morning visit to the cell he found the bear resting comfortably after his labour on the prisoner's straw bed; he fled precipitately, leaving the cell door open, and the bear marched out up the street into the fruit market; sellers and buyers ran off in all directions, leaving the bear to roam at his own sweet will amidst the fruit and vegetables; selecting a stall which contained fruit suited to his taste, he regaled himself, and was too busily employed to notice the approach of two blacksmiths, who, each armed with a pair of red-hot pincers, took hold of him by the ears and led him back ignominiously to his pit.

I went out to photograph the market but exposed no plate. A few years ago most of the people attending the market would have been in costume, now the costume is seldom seen; more may be seen on Sundays than on market days. There are many pictures round the town which might be secured if time and plate admit. That picture of the fountain was obtained in a back street near the Museum.

Interlaken is easily reached from Berne via Lake of Thun. A day may be spent profitably at the town of Thun, where the castle of Kyburg deserves notice. The photograph of Oberhofen was taken with the shutter as the steamer passed it; not having a finder I have not the precise view I intended.

At Spiez, further up the lake, there is a picturesque cluster of buildings which compose admirably for an instantaneous picture from the lake; possibly an equally good one may be obtained from the land.

The panoramic view of Interlaken is taken from the Hohbühl (cap off and on, f-34); it is in two sections—you cannot otherwise obtain the complete view—embracing the ends of the lakes both of Thun and Brienz, with the intervening plain and the mountains behind. The Jungfrau was capped, but a good view of that mountain, with the Rügen and meadow in the foreground, can be obtained from the windows of the Schweizerhof, and possibly from other hotels. The great triennial *fête*, the *Tire National*, was going on whilst we were there, and the houses and streets were decorated with flags, arches, and greenery; this, though it might have enhanced the appearance of the place in the eyes of residents, ruined it for photography. Each town sends its contingent of marksmen to contest for the prizes offered by the committee; they march in—rugged and bronzed-faced mountaineers and the less hardy-looking but more polished inhabitants of the town—each with his rifle slung over his shoulder, each company headed by its band; that of the Berne contingent was preceded by a bear, or, rather, a man in a bear's skin, who caused much amusement to the spectators by his antics. The photograph of the fair, which is carried on close to the shooting-ground, was taken under poor conditions as to light, when a good photograph with a shutter was out of the question.

A street of old chalets near the new post-office should be visited, and the market place of the ancient town of Unterseen, which looks as if it had drifted from the middle ages into the nineteenth century, will yield an interesting picture or two. Interlaken was apparently a suburb of Unterseen before it grew to its present importance. There is plenty of work to be done in the neighbourhood of Interlaken, especially in the direction of Lauterbrunnen and Grindelwald. The Rügen should be visited; numberless pretty vistas into the Lauterbrunnen Valley can be obtained through

breaks in the trees from the road which encircles the Rügen; beyond these is an exquisite view of the Unspunnen Valley, with the castle on the right and the mountains rising one behind the other, and bounded by the snow-clad peaks of the range in the distance. As good a point of view can be obtained of this valley from the Unspunnen wayside inn as from anywhere, and the light in the afternoon is the most suitable. Not far from this, at Wilderswyl, the next picture, *Haymaking in the Alps*, was taken; we had some difficulty in making the persons who appear in it understand that we wished to group them in the picture and send them copies of it—for we could not speak German, and they could speak nothing else; both difficulties were, however, got over ultimately, and their post-card, addressed to "Mr. Monkton Rectory," acknowledging the receipt of the copies sent them, is quaintly and prettily expressed. The literal translation runs as follows:—"Honoured Sir,—We have received your picture quite safely, which has given us great joy, for which we speak out to you the highest thanks; the whole family greet you friendly."

The Giesback Falls, on the Lake of Brienz, is within easy distance of Interlaken; the best, indeed the only complete view of them is to be obtained from the terrace of the hotel. Owing to the deep shadows of the woods on either side, a much longer exposure is necessary than would be the case on an open landscape; one of the two pictures before you was taken in the sunshine, the other under a cloudy sky, on June 20, between one and two o'clock; the former is under exposed two and a half seconds, the latter fully exposed (five seconds, f-34). Under the fall (next above the lowest, I think), under a platform partly cut in the rock and made out with wood strutted against the face of the rock and reaching underneath the fall to the opposite bank, with your back to the rock, the water falls from overhead in front of you, dashing on to the rocks beneath with a deafening roar; a projection in the rock above causes the water to divide, leaving a narrow space, through which this photograph of the lake, with mountains on the other side, was taken; in the middle distance a portion of the Giesback Hotel, and in the foreground the bed of the stream broken by rocks and flanked by the woods (exposure four seconds, f-34), are seen.

The next picture, the *Eiger*, was photographed from the Lauterbrunnen Valley on the way to Lauterbrunnen from Interlaken; the pretty composition of the mountain stream with the bridge over it and chalets and trees on either side, and the noble-looking mountains in the background, is taken nearer Lauterbrunnen; you cannot miss seeing it and recognising it as you pass.

The young lacemakers, with their huts and the Stanback in the background, will be recognised as having been taken in Lauterbrunnen. There was some little difficulty in getting them to group themselves effectively, but by dint of purchasing pillow lace in quantities of five yards for one franc (how can it be made for the money!) and a free distribution of nickel this difficulty was got over, but when the critical moment came and the cap was taken off, round went all the eyes to the central point of attraction—the lens tube. The pleasure to be obtained from gazing at a lens seems inexhaustible.

The Stanback was taken from the field opposite the principal hotel at Lauterbrunnen; the falls were in magnificent condition, any amount of water; no one who has seen them in August and September after dry weather can form any idea of their magnificence earlier in the year, when the torrent is swollen by the melted snow from the mountains.

W. MILES BARNES.

(To be concluded.)

Our Editorial Table.

THE GEM PNEUMATIC DROP SHUTTER.

ALFRED DREWET, Sidecup, Kent.

We have before us one of the above-named shutters. The cut fully

explains its *modus operandi*. It is cheaply though effectively made, and answers the purposes well for which it is intended.

PHOTOGRAPHIC ANNUAL AND COMPREHENSIVE CATALOGUE.

JONATHAN FALLOWFIELD, Lower Marsh.

THE nature of this thirty-third *Annual and Catalogue* is fittingly expressed by the term "comprehensive," for greater comprehensiveness in any collection of photographic appliances it is difficult to conceive of. Of the 335 pages comprising the *Annual*, no fewer than twenty-nine are devoted to lenses alone, these including the productions of all manufacturers of recognised high standing. As with lenses, so with cameras, detectives, enlarging apparatus, stands, shutters, and apparatus of every nature. There is no difficulty in finding within its pages anything one wants, or is likely to want.

Its compilation implies a great deal of labour, as everything is so well classified. We can very readily believe what is stated in the preface, that "it has been the result of several months of careful study." Most profusely illustrated, there has yet room been made for many practical hints and instructions in matters of interest in the art.

Much credit devolves upon Mr. Fallowfield for compiling such an excellent work of reference—a work comprising not alone goods made by this firm, but, as stated above, those of other eminent makers. The *Annual* sells at one shilling.

SIR DAVID SALOMON'S PHOTOGRAPHIC SLIDE RULE.

THIS is really an admirable little pocket companion, for, unlike so many other slide rules, it measures only eight inches in length. By its agency several useful photographic problems connected with lenses and diaphragms can be readily solved. Various values are represented on the scales; for example, one is devoted to the equivalent focus of lenses, another to the sizes of the aperture, a third shows the ratios, a separate one being devoted to the ratios in the Dallmeyer or decimal standard. The Photographic Society's standard is also given.

The slide rule is beautifully and accurately made by W. F. Stanley, Railway-approach, London Bridge, by whom it is also sold.

THE FACILE DETECTIVE CAMERA.

F. MIALL, Clapham Junction.

A DETECTIVE camera of an entirely new nature has recently been patented by Mr. F. Miall. In it no dark slides are used, but the plates are placed in a grooved box by means of an opening in the top of the camera. By simply turning a knob at the side the various plates drop, one after another, into another grooved box in the lower chamber, the knob racking one box in one direction, and the other the opposite way, thus ensuring the plate which is ready for exposing being always at the correct distance from the lens. After the plates (twelve) have all been exposed, they can be withdrawn from the grooved reservoir at the lower part of the camera. In external appearance the "Facile" resembles a well-made box, and, as we have said, the sole operation consists in turning one knob and pushing another, by which a plate will have been placed in position and exposed, the one previously exposed being, by the same movement, also removed and stowed away.

In our estimation the problem of the extreme of simplicity of action, coupled with efficiency, is solved in this "facile" detective. Indeed, simplicity is reduced to a minimum.

Foreign Notes and News.

PROFESSOR DR. HERRMANN of Königsberg is at present occupied with important experiments on the human voice. He employs for this purpose highly sensitive bromide of silver gelatine paper, on which the fluctuations of tone are recorded, the paper being moved forwards by a mechanical appliance. This method is not in itself new; but the curves traced by a thin ray of light are so delicate that they resemble a copper engraving, and at times are only visible under a powerful lens, although the curves to begin with were very much magnified.

THE *Photographisches Wochenblatt* has recently received from Herr H. Goltzsch a piece of orange-yellow glass which appears to cut off the blue rays just as well as dark-red glass. For his dark chamber, Herr Goltzsch causes the light in addition to traverse a solution of aniline yellow and some mandarin red, which appears to form a splendid light-filter. Such a solution cuts off the blue-green rays much better than the orange-yellow glass does, and the blue-green is a colour that has a very considerable effect on bromide of silver emulsion paper. Of course, in the case of all these light-filters, it is assumed that one is not working with plates artificially rendered specially sensitive to the light which they transmit.

THE little state of Weimar has agreed to offer prizes to the amount of three hundred marks, to be paid out of the Grand Ducal exchequer in connexion with the visit of the German Photographic Society to that town, which is to take place during the summer.

AN extensive photographic exhibition will also be held in Hamburg during the coming summer. The Hamburg Photographic Society recommends June as the most suitable time for paying a visit, as the exhibition will be then in full swing, and Hamburg and its neighbourhood appear to best advantage during that month.

AT its last meeting, on April 5, the Photographic Society of Dresden chronicled the completion of the fourth year of its existence as a society. This Association has this year been successful in establishing an Institute for the use of its members, where, in addition to the advantages of being able to attend lectures on photography and allied sciences, an extensive library and other conveniences are to be placed at their disposal.

MM. CARQUERO & GUILLAUMONT have arranged a chair in which a person may seat himself and, by pressing a button, be photographed instantaneously. The objective is placed in front of the chair and the portrait is delivered a few minutes after the sitting.

SWEDEN already possesses a publication devoted to photography, the *Fotografisk Tidskrift*, and though its life has not as yet been a long one, it has at any rate managed to reach its seventh number; its circulation is steadily increasing, and its popularity, since its adoption as the official organ of the *Svenska Fotografiamätföreningen* has received a considerable impulse. The current number contains an account of the last meeting of the above-named Photographic Society, under the presidency of C. G. V. Carleman. A proposal was made and adopted that the Society should establish a number of dépôts throughout the country, especially designed for the purpose of assisting amateurs.

THE current number of *Les Inventiones Nouvelles* gives an interesting account of a method recently invented in Russia for producing a photo-engraving direct on wood. The block employed requires, of course, previous preparation. Its pores are first filled with insoluble carbonate of copper, which is effected by boiling it in a solution of sulphate of copper and then in carbonate of soda. The block is thus dried and one of its faces polished, the back and sides being covered with a varnish of asphalt, the polished face being finally coated with sensitive gelatine. After photographing the subject to be engraved, the soluble remaining portions of the gelatine are removed by washing. The remaining portions, that is to say the design itself, is then coated with a layer of asphalt varnish, and the block immersed for an hour in concentrated nitric acid, and after that for another hour in sulphuric acid. By this means the wood is eaten away wherever it was left unprotected by the varnish, and on brushing it with a hard brush the design appears in relief. On drying and removing the asphalt with a little benzene, the block may be at once employed for printing.

PATENTS COMPLETED.

IMPROVEMENTS IN AND RELATING TO PHOTOGRAPHIC CAMERAS AND DARK SLIDES.

No. 6814. SAMUEL MARK CLARK, 54, Cheapside, London, E.C.—May 8, 1888. This invention has for its object the construction of photographic cameras in such a manner as to ensure strength and portability combined with the highest efficiency, at the same time that it shall be self-contained.

The device, according to my invention, comprises a box or case serving as a camera perforated centrally in front to receive the object lens, and furnished at the back with a closely-fitting hinged door and suitable fastening. A metal-flanged collar is secured within the perforation above referred to, into which takes the object lens, and which is held firmly in position preferably by a bayonet joint forming part of the lens tube.

In the roof of the box or case forming the camera is an opening in which is fitted a ground glass screen, beneath which is an enclosed chamber provided at the back thereof with a mirror fixed preferably at an angle of forty-five degrees. A second auxiliary object lens is inserted in the front of the camera immediately above the object lens proper, and centrally with the enclosed chamber aforesaid. A flat cover having folding side walls shuts down upon the ground-glass screen, and is held in position by a suitable bolt, catch, or equivalent, and in order to ensure a rapid opening of the cover a spring or piece of elastic is secured to the box and to the cover aforesaid.

An instantaneous shutter, which is pivoted within the box or case, is actuated by a slide, bolt, or equivalent passing through the side thereof, which, being drawn out against the tension of a spring, is caught and held back by a suitable spring catch, provision being made to vary the tension of said spring and thereby the speed at which said shutter closes.

The dark slide devised to be used in combination with the improved camera, according to my invention, consists of a frame having a central partition of any suitable material, preferably a web of woven fabric treated with any convenient substance to render it light proof. By this means I am enabled to enclose two plates in one slide, said plates being held rigidly therein by suitable clamps, bolts, or equivalent. An enclosing case or envelope is provided which accurately fits and encloses the dark slide, and is held firmly upon said slide by two small springs inserted in the sides thereof.

When packed for travelling, the object lens is secured in the interior of the camera by suitable clamps, and the auxiliary lens, in its telescopic tube, pressed in so as to lie nearly flat with the front of the camera. Three dark slides are provided, two being placed in the camera, one on each side, and held in position by suitable guides, the third slide being at the back of the camera in the position it would hold when an object is to be photographed. A suitable handle is attached to one side for convenience of carriage.

In using the apparatus, the object lens is removed from the interior and secured to its collar by the bayonet-joint-like attachment and the shutter and cover in the roof opened, the object being now projected upon the two ground-glass screens, the lenses are adjusted and the apparatus is ready for use, the sensitive plate being exposed by the withdrawal of the enclosing case of the dark slide from beneath the camera.

The auxiliary lens and enclosed chamber in the upper part of the camera is devised to ensure accuracy of the focal adjustment, it follows therefore that after the first adjustment of the lenses no further adjustment of the object lens is necessary, if the object projected by the mirror upon the screen in the roof of the case exhibits a sharp, well-defined outline.

The claims are:—1. In a photographic camera the adaption thereto of an auxiliary dark chamber and auxiliary lens substantially as and for the purposes set forth and shown. 2. The combination with the auxiliary dark chamber and auxiliary lens of a mirror for reflecting the image or object upon a focussing screen substantially as described. 3. In a photographic camera the combination therewith of the instantaneous shutter substantially as herein described, and the mode of and means employed for actuating same substantially as and for the purpose herein set forth and shown. 4. The utilisation of the interior of the box or case serving as a camera for depositing therein the various accessories for the purpose of transport substantially as herein set forth. 5. The improved photographic camera and arrangement of the various parts and accessories substantially as herein described and illustrated in the accompanying drawings.

IMPROVEMENTS IN PHOTOGRAPHIC CAMERAS.

No. 8193. HEINRICH MADEN and FRIEDRICH OERTEL, Augsburg, Bavaria.—June 5, 1888.

Our improved camera is rendered collapsible, and provided with special devices for regulating the position of the object glass, both as regards its elevation and as regards its distance from the sensitive plate.

The camera comprises a frame or main body, to the rear of which is hinged at the bottom the glass plate holder. The latter contains springs for retaining the glass plates by exerting a slight pressure, or for securing the slide which contains the sensitive plate. To the front of the camera body is secured the bellows, carrying in front the lens board or frame. For setting the lens at the required distance from the body we employ a special mechanism. This may consist of a toothed pinion and a rack sliding between two straight guides, and provided in front with a socket or nut for holding the spindle or post, carrying at the top the lens; or it may consist of a pair of lazy tongues or an expandible trellis work, the end of which is attached to the end of the bellows, and a double-threaded screw spindle held in suitable bearings and passing through a pair of screw nuts attached to the rear end of the said tongues. One end of the screw spindle carries a button for turning the same.

For adjusting the vertical elevation of the object glass or lens the post or spindle carrying the same is provided with a mechanism adapted to operate in any position of the bellows. This mechanism comprises a telescopic shaft provided near the front end with a pinion and near the rear end with a pivotal bearing. The pinion is in contact with a friction disc mounted on the lower end of the lens supporting spindle and provided with a screw nut through which the said spindle passes. The button which serves to turn the double-threaded screw mentioned above, and that which turns the telescopic shaft, are placed near together on the side of the camera.

The sides and the bottom of the apparatus are formed by hinged pieces of sheet metal.

For fastening the stand the apparatus is provided with two socket pieces on two sides at right angles to each other, so that the apparatus may be erected in two different positions.

AN IMPROVED PHOTOGRAPHIC "DETECTIVE" CAMERA AND CHANGING BOX.

No. 7942. THOMAS KERR, 52, Grosvenor Park-road, Walthamstow, Essex. May 31, 1888.

The sensitive plates are placed in the lower division of a changing box (which consists of two chambers communicating) in separate cases of metal or other suitable material, and pushed to the front vertically by a coil spring, and are thus exposed in rotation. Each plate after exposure is raised to the upper chamber by means of a vertical slide with catch at base, the slide being worked by lever arms on a shaft from the front of camera. The plates on reaching the upper chamber are kept in position by a second coil spring.

The plates are moved by the operator from one chamber to the other by a lever attached to the lever shaft, which may be kept inside or brought outside the camera case (preferably inside) as desired, and fixed to this lever is a handle passed through a slot in the side of camera case. A lock is adjusted to secure the lever handle when not in use.

For the purpose of registering the exposures a ratchet wheel, lever, and pawl are attached to the lever arms on the side of camera, so that simultaneously with the movement of each plate into position a numbered disc rotates and shows the number of exposures that have been made.

The object of the aforesaid improvements is to enable the operator to dispense with opening the camera when in use.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
May 6	North Middlesex Club	The Iron Room, Stroud Green.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

APRIL 25.—Mr. T. E. Freshwater in the chair.

The HON. SECRETARY drew attention to the prospectus of the great exhibition at York, in which photography will have a place.

Mr. F. P. CEMBRANO, in response to an invitation to speak on local development, stated that when he was in the south of Spain five or six weeks ago he photographed many specimens of Moorish architecture, and in the case of interiors the contrasts were usually excessively great; the foreground was often in deep shadow, with a brilliantly-lighted exterior seen through an archway or window. He tried less pyro and found some advantage in the negatives, but nothing proved truly effective until he adopted local development. He diluted his normal developer with from two to four times its bulk of water, at a temperature of 60° or 70° Fahr., and when the image showed he washed the plate under the tap; then he applied the developer to the shadow parts of the picture with a camel's-hair brush, whilst holding the plate slantingly that the surplus might run off and without flowing over the high lights. Every three or four minutes he washed the whole plate under the tap, and recommended the brush development; occasionally he flooded the whole of the plate with the developer. By these means he brought the different parts of the negative to the relative intensities required, occasionally also he treated parts of the plate with as much ammonia as the developer would bear. He had tried simple over exposure with this class of subjects, and found flatness and loss of detail to be the result. Applying restraining bromide to the high lights was not a method of local development which had answered in his hands. His pyro solution was made with sulphite of soda, four ounces; citric acid, two drachms; pyro, one ounce; water, ten ounces. He was from an half to three-quarters of an hour developing his best negatives. He handed round results in platinum type prints representing interiors in the Alcazar in Seville, the Alhambra, and other places of interest.

The HON. SECRETARY said that they were the finest prints he had ever seen of such subjects.

Mr. CEMBRANO, in reply to various questions, said that he had had no experience with orthochromatic plates; they would force him to develop in such a bad light. He used the quickest plates he could get, and extra thickly coated; he found that he could develop them all right in a proper bright yellow light. He preferred overcast, even rainy days for the photographing of interiors. His negatives were whole-plate size, and the size of the brush he used was a little bigger than the end of his thumb; the hairs gradually hardened under the action of the solutions. He had tried quinol several times but always went back to pyro, perhaps because he was most used to the latter.

Mr. J. R. K. WELLINGTON called attention to a published statement that prints could be toned with acetate of lead and hypo, and that some exist toned in that way which are now thirty years old.

Some members expressed the opinion that it probably amounted merely to sulphur toning.

Mr. Cox remarked that occasionally sulphur-toned prints were permanent.

SHAFESBURY PHOTOGRAPHIC SOCIAL.

APRIL 26,—Mr. Bull in the chair.

The evening was of a social nature, nothing technical being introduced.

HOLBORN CAMERA CLUB.

APRIL 26,—Mr. E. J. Wall in the chair.

About five dozen lantern slides were exhibited on the screen.

The CHAIRMAN, in reply to a query as to the best method of reducing over-printed silver prints, advised immersion in a solution of two grains of cyanide of potassium to the ounce of water, and then wash well; he also gave other methods, and finally agreed to give a demonstration at the Club Room on May 3 on the subject of *Ischromatic Plates*.

Miss Powell, Messrs. Edwin Hodges, Alfred Hodges, and Jones were elected members.

BURNLEY PHOTOGRAPHIC SOCIETY.

APRIL 24,—Dr. Brumwell (Vice-President) in the chair.

Messrs. V. Dunkerley, H. Jackson, and Dr. Stuart Hallows were elected members.

The CHAIRMAN read a paper entitled *With Poets, Artists, and Antiquaries at Bolton Abbey*, in the course of which he described the Abbey when standing in its full grandeur and beauty, as surmised by the antiquaries from what remains of the ruins and from ancient manuscripts. He also mentioned the visits of poets to it, and quoted from Wordsworth, Rogers, &c., and finished with a description of artists' visits to it, describing their pictures and locating their standpoints.

At the end of the lecture illustrations were projected on the screen, the pictures comprising several from negatives by members of the Society.

The next monthly meeting will be on May 29, when the Hon. Secretary (Mr. William Sutcliffe) will give *A Few Days at Scarborough with the Camera*.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

APRIL 25,—Mr. A. W. Beer in the chair.

Messrs. Percy Allman, J. W. Ashurst, George Bredding, H. J. Bromilow, John S. Brown, Oswald E. Brown, G. L. Burton, John Byrne, H. Cunningham, Edward Edwards, W. M. Faltin, E. Gibson, Richard Hartley, Frank Howard, D. A. Hunter, Thomas T. Irvine, S. H. Johnson, A. J. Keay, Thomas S. Lamb, George F. Mason, Charles W. Mayne, J. R. Moir, G. Banner Newton, Charles B. Reader, J. Sheard, Isaac Smith, James S. Webster, and Mrs. J. T. Smith, were elected members.

The PRESIDENT announced that Mr. W. Hughes would lead the excursion to Rossett on May 4, also that a second Smoking Concert would be given on Thursday, May 2, at which the musical arrangements would be under the charge of Mr. Nicholls.

The HON. SECRETARY read letters from the Hon. Secretary of the Paisley Photographic Society, offering exchange of lantern slides, and from Mr. Thomas Comber, J.P., regretting absence from Dr. Paul's demonstration, and sending for exhibition a transparency of a diatom, *Pleurosigma angulatum*, magnified eighteen hundred diameters.

A question from the box on cloud negatives was answered by Mr. Beer and several other members. The general opinion was that it was best to use slow plate, small stop, and rapid exposure.

Mr. F. T. PAUL, F.R.C.S., gave a demonstration on the mode of making micro-photographs, showing how the apparatus can be adapted from an ordinary camera and microscope. He remarked that he thought the value of micro-photography had been exaggerated; that for low powers it was invaluable, but that when very high powers were employed he preferred making drawings. He employed a microscope of the Continental construction with short body, removing the eyepiece, and advised the use of the lower powers, gaining magnification by increased length. The one inch and half inch objectives answer well, the quarter inch and higher powers require a condenser, but then the light begins to fail. He employed an ordinary long-focussing half-plate camera, placing it with the microscope and illumination upon a large board, upon which is placed a beading to keep the camera straight, also another to fix place of the microscope. Focussing is effected by means of a long rod, with a blind-roller wheel at the end and a catgut band driving the fine adjustment of the microscope. The microscope and camera were connected by a box, and light prevented from entering by velvet cloth. As regards the correction of the object glass, there were special apochromatic objectives made by Zeiss, but these were very expensive and for low powers unnecessary. He had not found isochromatic plates to work very well, and preferred a fairly slow ordinary plate. The light employed was an ordinary blow-through lime jet and a very small diaphragm. A paraffin light takes from several minutes to half an hour. Sunlight is best, but requires a heliostat. He placed a microscopic slide on the stage and exposed for thirty seconds, using one inch objective. The resulting negative was developed by Mr. J. H. Day, and proved quite a success.

Mr. V. C. DUFFIELD then read a paper upon the "Actinograph," an instrument invented by Dr. Hurter and himself for calculating photographic exposures [this will appear in a future number].

A number of lantern slides, the work of Dr. Paul, were shown, also the negative just produced.

At the close of the ordinary meeting the meeting was made special, and the revised rules, with slight verbal alterations, unanimously passed. The principal change in the rules raises the entrance fee for all new candidates to twenty-one shillings.

BATH PHOTOGRAPHIC SOCIETY.

APRIL 24,—Mr. W. Pumphrey (President) in the chair.

The CHAIRMAN referred to the loss the Society had sustained in the death by drowning of Mr. Janvrin.

Mr. G. F. POWELL detailed the interest taken by deceased in the Society, of which he was a founder, and spoke of the dangerous condition of the coast

where the sad accident occurred; and, upon motion, a letter of condolence with the family was ordered to be sent.

Messrs. Hensley and Munday were elected members of the Society.

A series of large photographs of Niagara, representing both summer and winter, were, through the kindness of Miss Ashley, exhibited.

Mr. J. DUTTON drew attention to some negatives of Salisbury Cathedral made by the wet collodion process about fifteen years ago on 18x14 plates. It was said to be a difficult subject at any time. Some negatives made by means of the old collodio-albumen process were shown by the same exhibitor, and the peculiar colour and slowness of such negatives were remarked upon.

The President handed round for inspection two sets of photographs, the result of a month's tour in Italy and in Switzerland. The prints were shown to illustrate the capabilities of film photography, and the mode of mounting adopted was that of attaching the boards with glue whilst the prints were in contact with sheets of ebonite, which, when stripped, left the picture with a highly-glazed surface.

Mr. FRIESE GREENE said he had lately found that it was quite possible to destroy the effect of light—the latent image in a plate by the influence of electricity, after which the same plate was again ready to be acted upon by light. He then handed some notes to the Chairman, which were read as follows:—Acids and alkalies combine through being in opposite states of electricity. If you put the acid in a positive state of electricity it refuses to combine with an alkali. You will find the developer will not act if it is in an electrified state on an exposed sensitive plate, and if a plate is left for two minutes in a weak acid solution which has a current of electricity passing through it the latent image cannot be developed, but you can wash and expose the plate again; so by this you can extract the latent image and still use the plate again. Suppose two particles holding a different amount of energy or electricity had another particle come in contact with them it would combine with the one with the most energy or electricity. Suppose you have two particles the same as above and two particles instead of one come in contact with them all holding different amounts of energy or electricity the two particles with the most energy would combine.

Mr. AUGUSTUS F. PERREN next demonstrated the treatment of platinotype prints by the hot bath process of development. Having pointed out the absolute necessity to keep the sensitive paper dry and the variations in temperature of the developer allowable under fixed conditions, proceeded to pass a number of exposed papers over a hot bath of potassic-oxalate solution. These were afterwards soaked in acidulated water and then handed round. The pictures, mostly local views, were much admired, as also were some finished specimens.

After a brief discussion the proceedings terminated.

ON Thursday, April 25, the first outdoor meeting took place at Farleigh Castle. There was a good attendance, and all the chief points of interest in that vicinity were photographed. At half-past five p.m. the party assembled at the Houlton Arms, where a substantial tea was provided, over which the President presided.

The next excursion, May 30, will be to St. Catherine's.

WEST KENT AMATEUR PHOTOGRAPHIC SOCIETY.

APRIL 26,—Mr. Pringle in the chair.

The President showed a travelling lantern he had had made. By packing the condensers (four inch) and front lenses inside the body of the lantern, the whole thing packed into a box about six inches cube. This lantern had no chimney, the roof being specially jacketed to obviate the necessity for one. It was much admired as a marvel of compactness and portability. He also showed a camera which had been built to design. One special feature was an arrangement whereby the centre swing could be obtained without the use of the extra weight of wood-work usually put on the back for this purpose. A patent box for carrying plates was also shown by Mr. Pringle. This had a simple arrangement of pressure springs which had the effect of making the plates carried in it practically one solid block of glass, thus avoiding all fear of breakage.

Watson's detective camera was next shown by the Secretary who also handed round a specimen copy of THE BRITISH JOURNAL OF PHOTOGRAPHY, and Pallowfield's new catalogue which had been forwarded for the use of the members.

Mr. Hawkins exhibited a number of stripping film negatives taken on a cycling tour.

Mr. PRINGLE then gave a short address upon *Quinol versus Pyro*. He had made a series of exhaustive experiments comparing the merits of the two as developers of negatives. The result of them was in favour of pyro. It has been said that quinol gives negatives of a wet plate character and this has been advanced as a fact in its favour. Now the distinguishing characteristic of a wet plate negative is clear glass in the shadows. This is a thing we ought to be very careful to avoid. Clear glass would give absolute blackness in the resulting print, there being no such thing in nature as absolute blackness, the very deepest shadows in a view possessing detail, and this we want to reproduce on our negative. Now quinol will develop the high lights to an abnormal degree of density while leaving the shadows unaffected, and this great density in juxtaposition to clear glass while being entirely wrong for nearly all classes of work is just right for one branch, viz., copying engravings, &c. Another great fault of quinol in landscape work, is that it does not render distance or atmosphere. Many workers liked this developer because it gave such "pretty negatives." These were to be guarded against, as however nice they might look as a negative, it was impossible to obtain a good print from them. While being unsuitable for negatives, it was, however, a most excellent developer for transparencies.

After a short discussion the proceedings terminated.

NORTH SURREY PHOTOGRAPHIC SOCIETY.

APRIL 9.—Annual General Meeting.

The HON. SECRETARY submitted the audited accounts for the past year, showing a balance in hand of 124 13s. 4d.

The following gentlemen were elected to form the Committee for the ensuing year:—Messrs. J. Morrish, W. H. Baldwin, F. J. Bright, J. Larcombe, W.

Rice, W. A. Rouch, and Dr. Charles Gross, one of whom to be Secretary and Treasurer, to which office Mr. J. Larcombe was appointed at a subsequent meeting of the Committee.

The next meeting will be held on Tuesday, May 7, at eight p.m., when Mr. W. Thomas will read a paper, illustrated by lantern slides, on *The Coast of Yorkshire*.

NOTTINGHAMSHIRE AMATEUR PHOTOGRAPHIC ASSOCIATION.

APRIL 29.—Mr. H. Blandy, L.D.S. Edin. (President), in the chair.

Mr. George Smith was elected a member.

Mr. POLLARD GRAHAM, of Derby, gave a demonstration entitled *The Relation of Exposure to Development*. The experiments were directed chiefly to showing the immense latitude in the exposure possible with development suited to the occasion.

Four plates had been exposed during the day at Bestwood Lodge by Messrs. R. S. Armitage and George Smith, the plates used being the Ilford, and exposures being given of one, three, five, and twenty seconds, the three seconds' being the correct exposure. This plate was developed by Mr. Armitage for comparison with the other three, after Mr. Graham's development, and it is satisfactory that Mr. Graham was successful in securing all as good negatives, with little trace of either under or over exposure. Another experiment was by contact exposure, excellent negatives being secured.

The PRESIDENT thought that he had made good his claim to the possibility of getting good results from widely diverging exposures, and had shown the members what could be done by studying the conditions under which they exposed, and that it rested entirely with themselves if they lost a plate through either under or over exposure.

DERBY PHOTOGRAPHIC SOCIETY.

APRIL 27.—The members of this Society held their first outdoor excursion of the season at Ashby-de-la-Zouch, where, by the kind permission of J. Hemsley, Esq., they were enabled to photograph the ruins of the Castle from the grounds of the Manor House. Upwards of sixty plates were exposed, and some excellent negatives obtained. The weather being exceedingly fine a most enjoyable time was spent. Mr. Hemsley kindly entertained the members to light refreshment during the afternoon, and before returning home the party sat down to an excellent repast, provided by Mr. Boden, of the Queen's Head Hotel.

MANCHESTER PHOTOGRAPHIC SOCIETY.

APRIL 11.—Mr. Alan Garnett (Vice-President) in the chair.

Messrs. T. Worthington Wright and Edmondson were elected members.

After replying to technical queries from the question box, the subject of the evening was introduced by the HON. SECRETARY (Mr. W. I. Chadwick), who gave a lecture on *Stereoscopic Photography*. In the course of his remarks the reason why prints taken direct from a stereoscopic negative must be transposed, the size of picture most suitable for stereoscopic observation, and the advantages derived by using lenses of longer or shorter focus (depending upon the nature of the subject), were fully explained, as was likewise the construction and principles of the refracting or lenticular stereoscope. The most approved method of mounting and trimming stereoscopic paper prints was then described, and some simple appliances to facilitate the work were exhibited. The trimming and mounting of stereoscopic pictures was a matter that had been sadly neglected in the old days of the stereoscope. Thousands of these pictures have been placed upon the market which, from defective mounting, were absolutely worthless. Attention to this detail was, therefore, of the utmost importance. Mr. Chadwick illustrated his remarks by three stereoscopic slides printed from the same negative: No. 1 was perfect, Nos. 2 and 3 were printed and mounted incorrectly and could not be made to coalesce. Beautiful as properly mounted paper slides undoubtedly were, the best of them fell far behind good transparencies printed upon glass, and it is this latter class of stereoscopic work that mostly engage the attention of amateurs just now. Indeed, with the reliable dry plates made for the purpose by Mawson & Swan, Thomas, and others, and a few simple appliances, glass transparencies were almost as easy to produce; and as the work could be performed in the evening (daylight not being required as in paper printing), this branch of photography was admirably suited to amateurs, and with whom it was rapidly becoming popular again. The lecturer then exhibited and described a very simple printing frame which he had constructed by which stereoscopic transparencies could be transposed and printed in contact. Camera printing was, however, the best of all methods, the advantages of which were explained. With the apparatus shown (a simple and inexpensive addition to the ordinary binocular camera with which the original negatives were taken) the printing and transposing could be done by one operation, all the adjustments made and viewed on the ground glass of the camera before exposing the plate.

At the conclusion of the lecture Mr. Chadwick replied to many questions.

The formal meeting was then adjourned and the members gathered round the tables to inspect a large and interesting collection of stereoscopic pictures. Six charming slides sent by Mr. Stroh (instantaneous street views in and about London) excited universal admiration; and a collection of highly interesting slides sent by Mr. J. Traill Taylor, Editor of THE BRITISH JOURNAL OF PHOTOGRAPHY; on the back of each slide was written the particulars and particular features. Mr. H. Smith exhibited prints from two negatives by Mr. Chadwick which were shown at the previous meeting; one was a glass plate negative, the other was taken on a Carbutt flexible film under precisely similar conditions; the print from the glass negative was decidedly the best. Mr. Clayton exhibited a very nice series of transparencies in a revolving stereoscope, but the climax of enthusiasm was reached when Mr. Chadwick exhibited several of the choice composition transparencies of the late Charles Breese, in which were introduced, over breaking waves, birds on the wing in mid air, distant clouds, sunset and moonlight effects, &c.; and, notwithstanding the lateness of the hour, many of the members remained to enjoy a portion of the series of the Royal Jubilee Exhibition, Manchester, taken by Mr. Chadwick for the Executive Committee.

BRIGHTON PHOTOGRAPHIC SOCIETY.

APRIL 23.—Mr. W. Jago, F.C.S. (Vice-President), in the chair.

Mr. G. PERREN read a paper entitled *A Short History of Photography from its Earliest Stages*, and handed round several fine Daguerreotypes executed by himself, which were much admired by the members present.

Mr. Jago exhibited an ingenious detective camera. Several fine negatives of Sussex churches were exhibited by Mr. S. B. Harlecastle.

At the next meeting, on May 14, Mr. George Foxall will read a paper on *Landscape Photography*.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

APRIL 25.—Mr. W. J. Harrison, F.C.S., in the chair.

Messrs. R. H. Edney and Alfred Reading were elected members.

The question box contained:—"Can the Sciopticon be thoroughly recommended as a thoroughly efficient mineral oil lantern? Is there any better form of oil lantern? Is a double-wick or a circular-wick lamp best adapted for showing lantern slides?"

The CHAIRMAN spoke in favour of the Sciopticon with double wick; had used the same for some time, and was thoroughly satisfied with it.

Mr. C. J. COTTELL: The four-wick lamp is very effective, but wants careful manipulation, especially with regard to the great heat it gives out.

Mr. F. GREENING had used the circular wick with advantage.

Mr. WALTER GRIFFITHS remarked that *Lantern and Lantern Work* should be a subject chosen for a Tuesday social evening in the Club Room, and that the suggestion be referred to the Council.

The following half-day excursions were recommended by the Excursion Committee:—May 4, Yardley Wood; May 18, Dudley Castle; June 1, Coleshill and Mazatoka Castle.

Mr. B. KARLESE then introduced the subject of *Cameras and Appliances*. In the course of his remarks he said:—

In selecting a camera the chief consideration usually is its cost and the purpose to which it has to be applied. For amateurs the range of usefulness should be as wide as possible. The remarks I shall make this evening will be confined chiefly to the apparatus used by myself (which you see before you) and my experience with the same. This is a tourist's camera for whole-plate size, which I consider to be the largest limit to use with convenience and comfort in landscape work. It was made to my own specification, and, as you see, is of the square form, made of mahogany, and with leather bellows, and parallel throughout, closes to a focus of four inches and extends to twenty-six inches; this is ample range for the lenses usually supplied for this size of plate, my own lenses being from eight and a half to twenty-two inches focus. The focussing is by rack and pinion, and operates from the back, which is preferable to the front focussing, both as regards convenience for manipulation when using a long-focus lens and the advantage of having the baseboard out of the way for a wide-angle lens and the use of a drop shutter. The front has vertical and horizontal movements, the back is firmly supported in a vertical position by a long rod running from a groove in the baseboard and secured in position by screw nuts at the top; it is reversible, and the focussing screen hinged to it in such a manner as to fold completely out of the way when the plateholder is in position; it swings from the centre, also from either side, giving in each case a range of over an inch. The arrangement for inserting the plateholder, you will observe, is of the simplest form—a groove running the length of the back with a corresponding lip on the plateholder to drop into it, and a spring catch on the opposite side to secure it to the camera, the whole being reversible in two seconds. The plateholder carries two plates, is of the book form, and the shutter double-hinged, so as to fold completely out of the way. When the camera is closed the baseboard folds upon the focussing screen, so as to entirely protect it; and you will see that to open or close the camera only two operations are necessary, those of releasing or fixing the side struts and withdrawing or closing the back to the position required on the baseboard; and, most desirable of all the advantages, there is not a single loose screw or pin in the whole apparatus, a *sine qua non* to the forgetful photographer. Nothing has been sacrificed for the sake of weight, and I should advise you rather to select a substantial apparatus than to be looking out for phantoms and featherweights which when set up in the field are vibrated by the softest breeze. With respect to levels, rather than fix them to the camera I prefer to carry a pocket spirit level of about three inches bearing a small plumb line, which with the compass, you will notice, are conveniently disposed of in this small case. When travelling I pack the cameras in one case, the plateholders in another, and the tripod in another; I am then able to carry the whole comfortably myself or to accept the services of a companion without the risk of fatigue on him. The tripod I have here is of the sliding pattern, and when set up to its full extent elevates the camera to a height of five feet six inches, enabling me to see the focussing screen without stooping, at the same time I can reduce it to three feet when necessary. Having given you a full description of the apparatus suitable for landscape work, I may mention mine has been in use for two years, and I have not found on the beach, the mountain, or in the field that any further additions have been necessary.

A long discussion followed, and a number of different cameras and apparatus exhibited and explained by the members who exhibited them, and their respective merits were debated upon.

Messrs. Marion & Co., of London, had kindly sent down McKellen's detective camera and Krugener's book camera, which were shown by Mr. B. Karlese.

The evening proved a thoroughly interesting and instructive one.

The subject of next meeting's paper will be *Composition*, by Mr. E. T. Cox.

Correspondence.

Correspondents should never write on both sides of the paper.

PAPYROXYLINE.

To the Editor.

Sir,—Please allow me in the columns of your JOURNAL to thank Junius for the full information he has given me regarding papyroxyline, and although, without having tried it, I think it will be useless for my

purpose, I shall be glad to accept Junius's kind offer to send me samples of papyroxyline which burn at different speeds. I shall also very much appreciate any hints regarding the preparation of the same.

As to Junius's remarks anent to yellow light mixed with white having no deterrent action, I must admit that his theory seems sound. But my experiments have led me to the opposite conclusion. When I used a given quantity of magnesium powder mixed with pulverised gunpowder, and the same amount of magnesium mixed with chlorate of potash, I found that the latter gave a much better exposed negative than the former, and that is the reason of my partiality for using a substance burning with a white light for consuming the magnesium powder. Trusting I have not encroached too much on your space—I am, yours, &c.,

W. GUTTENBERG.

29, Triangle, Clifton, Bristol, April 29, 1889.

CAMERA CLUB EXHIBITION.

To the Editor.

SIR.—We are requested by the Committee to ask if you would kindly note that the third of the series of one-man photographic exhibitions at the Camera Club will be open for private and press view on Monday evening, May 6, at 8 p.m.; and on and after Tuesday, May 7, it will be open to visitors on presentation of card. The exhibition will continue for about two months.

The object of this series of exhibitions is to bring together in turn, as already stated in connexion with the Sutcliffe and Tolley Exhibitions, representative collections of the work of the best photographic artists.

By the kind co-operation of Mr. J. Gale we are enabled to exhibit a representative set of his photographs. These pictures are chiefly landscape, and landscape with figure, and are printed in platinum and in silver processes.—We remain, yours, &c.,

G. DAVISON,
E. G. SPIERS, } Hon. Secs.

Camera Club, 21, Bedford-street, W.C., April 30, 1889.

Answers to Correspondents.

* Communications relating to Advertisements and general business affairs must be addressed to "H. GREENWOOD & Co.," 2, York-street, Covent Garden, London, W.C.

All matters for the text portion of this JOURNAL, including queries for "Answers" and "Exchanges," must be addressed to "THE EDITOR," 2, York-street, Covent Garden, London, W.C. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.

PHOTOGRAPH REGISTERED:—

A. E. Smith, Bristol.—Photograph of Lord Salisbury at Bristol.

ALPHA.—Yes, either will do.

J. P.—See reply to "H. Bruton."

KEMPSSELL.—Inquiries are being made.

W. AND E. ALCOCK.—Received. Thanks.

GALWAY.—See reply to "Work" in this issue.

H. C. SUMMERS.—We are unable to give the address you require.

CLUB MEMBER inquires if guni sandarac is soluble in alcohol.—Yes.

CHEMIST.—All methods are employed according to their requirements.

F. W. HART.—Your letter came too late for insertion in this week's issue.

MARSH AND TIDY.—Hill Brothers, 43A, Milton-street, E.C. Letter forwarded.

DOUBTFUL.—Gelatin plates, not collodion, are now universally used for studio work.

J. JAMES.—Your long letter received, but it is of a subject totally unsuited for our pages.

SPENCER NICHOLL.—Yours is not a matter to answer in this column. We will reply privately.

BLUENOSE.—The projection of powdered magnesium through a powerful flame is about as rapid as any.

L.—Not knowing the make of plate, or the treatment the negative received, it is impossible to give an opinion.

R. L.—Pure lead may be obtained by reducing nitrate of lead with charcoal. As the rule, the softer the lead of commerce the purer it is.

WORK.—Please send your address, which has been destroyed, as we have a communication for you on the subject about which you wrote.

A. S.—1. Fume the paper well with ammonia before printing.—2. The emulsion spoken of will do equally well for either lantern slides or opals.

PHOTOGRAPHER says: "What will be the result if the combinations of a lens are brought closer together?"—The image would then cover a larger field.

M. M.—The position of the stop in your single-view lens is evidently not correct; move it nearer to the lens and you will obtain the effect you desire.

T. S. R. writes: "Can you tell me if there is any metal which, when heated, will contract, and will expand when cooled?"—Take lead, nine parts; antimony, two parts; bismuth, one part. This expands as it cools. It is used for stereotyping purposes.

L. M.—1. Better eschew the side swing altogether, unless the camera is a large one.—2. The side swing for the back and that for the front answer a similar purpose.

REV. J. C. BROWN asks what "O. H. E. Cy (L⁴)" means, and if the Company burn in photographs.—In reply: It is "The Old Hall Earthenware Company (Limited)," Hanley, Staffordshire. As regards the burning-in of photographs, if only the firing is meant, I should say they do. The managing director of the Company is Mr. W. F. Drew.—W. A. MEIGH.

WILLIAM RULE asks if there is any means whereby a blue print can be rendered of a brownish tone?—Immerse the print in the following—borax, two and a half ounces; hot water, thirty-eight ounces; when cold add a small quantity of sulphuric acid and a few drops of ammonia, then add about one hundred and fifty grains of gum catechu.

PRINTED.—Make a strong solution of potassium sulphide (liver of sulphur), and of this pour enough into the old fixing solutions until the silver is precipitated, which will be in the form of a dark mud. When the whole of the barrel has been filled, take a little out and filter it, and ascertain by a drop of sulphide whether the whole has been precipitated. Do not add more than is absolutely necessary.

H. BRUTON.—The formula recommended by Mr. Lyonel Clark consists of:—No. 1, ammonia one part, water forty-nine parts; No. 2, sodic sulphite a saturated solution; No. 3, potassium bromide twenty grains, water one ounce. To develop, fifty minims of No. 1 are added to eighty minims of No. 3 and sixty minims of No. 2. About one and a half grains of pyro are placed in the developing cup and the whole made up to two and a half ounces. When all details are out, more pyro and ten minims more of No. 1 are added.

ANXIOUS complains that he has a difficulty in getting his toning bath to work after it has toned a few prints, and the addition of more gold does not improve matters to any great extent. He asks if a brass tube he has in the corner of the wooden dish he uses may have any influence on the solution.—If the solution be brought into contact with metal the gold will be thrown down. This, no doubt, is the cause of the trouble. The two prints enclosed bear evidence of careless manipulation. One is terribly yellow through imperfect fixation.

FLORENCE writes: "1. I took some photographs (views) the other day with a wide-angle lens and developed in the usual way, and have got good clouds in all of them; do all wide-angle lenses act the same?—2. I have a lot of sensitised paper gone bad; I saw a receipt for making it work the same as new, but cannot find it now; can you give me a way by which I can make it work all right?"—1. It is a matter of relation of aperture and stop irrespective of the class of lens.—2. There is no way known by which deteriorated sensitised paper can be restored to its pristine quality.

S. W. writes: "Having read of the platinum silver printing in which an image is first printed on plain paper in silver and then brushed over with Willis's cold bath developer, I tried it and got excellent results. Then I took ordinary ready sensitised albumenised (silver) paper, and printed till a little darker than I should have done for gold toning, &c. I washed it well till no clondiness appeared in water, and then brushed it over with Willis's cold bath developer as above. Very slowly it changed, and in three or four minutes my red print was a magnificent, rich, jet-black colour, and when finished it looked like a true platinum print, having all the delicacy and beauty of an albumen silver print. Now, what I want to know is this, Am I correct in considering such prints absolutely permanent as a true platinum print? I see that in Willis's platinum process the image is only pure platinum, but in this process the image is not of pure platinum. In fact, it seems to me that the platinum has only played the part of the gold toning bath."—The image will consist entirely of platinum only when the toning is carried on until the whole of the silver has been substituted by the platinum. As our correspondent has been working, the process has been analogous to the ordinary gold toning, and the results cannot be expected to be more permanent.

MR. W. TYLAR, Birmingham, has sent us a sample of a white ink that he has introduced for writing on dark paper, such as the masks of lantern slides. For this purpose it is admirably adapted.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, May 8, 1889, will be on *Fixing Negatives and Prints*. Saturday outing at Waltham Abbey. Train from Liverpool-street at a quarter-past two.

THE copartnership concern of M'Ghie & Bolton, Manufacturers and Dealers in Photographic and Scientific Materials and Chemicals, No. 47, West Nile-street, Glasgow, has been dissolved by mutual consent. The two gentlemen named will in future conduct similar separate businesses each under his own name.

OFFICERS OF ST. LOUIS CAMERA CLUB.—Elected April 2, 1889.—President: Mr. Robert E. M. Bain.—Vice-President: Rev. Charles M. Charroppin, S.J.—Secretary and Treasurer: Mr. William M. Butler, 2636, Osage-street.—Executive Committee: Messrs. Eliot C. Jewett, John W. Dunn, John B. Holman.—Lantern Slide Committee: Messrs. Henry B. Alexander, Henry Blattner, Robert E. Collins.—House Committee: Messrs. John F. Valle, William M. Bulkley, Henry M. Holland.—Membership Committee: Messrs. Charles M. Alexander, Charles W. Melcher, Samuel B. Ball.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1514. VOL. XXXVI.—MAY 10, 1889.

THE STRENGTH OF ALKALINE SOLUTIONS.

WHEN we wrote last week on this subject we were under the impression we had given all the information that was needful, although in a brief form; but queries from several correspondents tend to show that we have left something undone, and that it is necessary to explain the method of calculating the results of the quantitative analysis. We shall therefore do this in as succinct a manner as possible.

Let us first suppose we have a sample of alkali—let it be liquor ammonia, carbonate of soda, or carbonate of potash—the real value of which we do not know. The ammonia may and does vary in strength very greatly from mere evaporation of the gas. Carbonate of soda exists in commerce in combination with very different proportions of water of crystallisation as well as in the anhydrous state; besides which, crystals originally containing a definite proportion of water may become unreliable from loss of a portion of the water by efflorescence, in which case they possess an additional strength. Carbonate of potash—one of the most deliquescent of salts—can scarcely be relied upon as a definite compound at all unless newly dried, so variable is the proportion of its contained moisture. There is, therefore, every need to adopt measures for the accurate estimation of all such substances. When we speak of accuracy, however, in this connexion, it must be understood that analytical exactitude is neither necessary nor intended, but simply a degree of what the chemist would consider “approximation,” though it is ample for all the purposes of the photographer.

Let us suppose we have a sample of one of the above-named substances that requires examination. Let it be taken in its ordinary form as obtained commercially, that is, without any drying or other special preparation, but just as procured and as it will be used. From the bulk weigh out carefully ten or, better, one hundred grains; the larger quantity reduces the proportionate error in weighing. We will suppose that we are operating upon a sample of carbonate of soda which must be dissolved in water to make up precisely two drachms or two and a half ounces, according to whether ten or one hundred grains are dealt with.

If the means be not at hand for accurately measuring small quantities of liquid, it will be better and perhaps easier to make the solution by weight. In this case counterpoise a suitable vessel in the ordinary scales, and having introduced the weighed quantity of carbonate of soda carefully, make up the weight to ten times that of the original salt with distilled or rain water. Thus, if one hundred grains of carbonate of soda are taken, add carefully, especially towards the last, sufficient water to just turn the scale at 1000 grains. The liquid then

contains one grain of the original alkali in each ten grains by weight of solution, and this will be found a more accurate method of working than by measurement.

Of the solution thus made we will take for actual trial either one drachm by measure, if it has been made by measure, or one hundred grains by weight, if the latter plan has been adopted; but there must be no mixing up the two systems of weighing and measuring. We will take, for example, one hundred grains of the solution made by weight and containing ten grains of the original salt.

Let this be diluted with, say, an ounce of water, and a few drops of litmus solution added to tinge it a decided blue, without imparting any great depth of colour. Having now filled the burette with the standard solution of acid of the strength of 126 grains in 1000 measures, and with the precautions described last week commence very carefully to run it, a few drops at a time, into the weighed portion of alkali solution. At first there will be no change in colour, except, perhaps, just at the surface where the acid first touches, and this quickly disappears as the contents of the flask are agitated. But presently the contents of the flask change from the original blue colour to a sort of nondescript pinkish purple, showing that one molecule of the soda in the Na_2CO_3 is saturated with oxalic acid, and that the liberated carbonic acid is still remaining in the solution in the free state or, in combination with the remaining molecule of soda, as bicarbonate, NaHCO_3 .

If the solution is now boiled for a few seconds the free CO_2 will be driven off and the blue colour restored, when the further addition of the acid solution may be resumed. By repeatedly reapplying heat to the now hot solution the liberated carbonic acid is quickly driven off after each fresh addition of standard acid, and soon a point will be reached at which the pinkish purple tint gives place to a full red, and boiling fails to alter it. Then the reaction is complete, the whole of the carbonic acid has been displaced, and the test is finished.

A chemist would work upon probably a much smaller quantity of alkali and with a far more dilute solution of acid in order to obtain closer accuracy, but, as has been already said, for photographic purposes the proportions given above will serve every useful end. Still some care must be exercised in adding the test acid and in getting rid of occluded CO_2 , otherwise the point of neutrality will be missed. One or two trial operations will, however, give the necessary practice.

Now for the method of calculating the result. Let us suppose that 37 c.c. or divisions of the standard acid have been used. The latter solution contains 126 grains in each 1000 divisions, therefore 126×37 , or 4662 grains, is the

quantity of oxalic acid consumed. If we now turn up the table of equivalents in the ALMANAC we find that the equivalent of crystallised carbonate of soda is 286, and that of oxalic acid 126. Making a rule-of-three sum of it, we find that the original ten grains of carbonate employed, if strictly accurate in composition, would require, as shown, 4.404 grains of oxalic acid: thus—

$$286 : 126 :: 10 : 4.406.$$

We are, therefore, a little over the theoretical quantity, proving that the sample tested has lost some portion of its water of crystallisation. If liquid ammonia, or carbonate of potash, or even anhydrous carbonate of soda had been tried, instead of "washing soda," the result would almost surely have been that the quantity of standard acid used would have been below the theoretical figure, or that they contained less than the proper proportion of alkali.

In testing the caustic alkalies the procedure is precisely the same, only there is no necessity, except in the case perhaps of potash, to resort to boiling to get rid of the carbonic acid. Potash has such an affinity for CO_2 , that if the sample has been carelessly kept it will be certain to have absorbed an appreciable portion, which will have to be allowed for in development.

From the results obtained in this manner from a known quantity of the substance it will be easy to make up solutions of definite and uniform strength at any time, and to make, further, solutions of different alkalies all having the same degree of alkalinity. In our ALMANAC for 1885 will be found an article on this subject, which may be worth perusal now that the caustic alkalies are coming into use with hydroquinone.

COMBINING TWO OR MORE NEGATIVES.

In a previous article, see page 278, *ante*, we explained how negatives can easily be combined, provided they are, in the first instance, taken in the film form. But as every one who may at times be desirous of making a combination picture does not take film negatives, we shall here describe how the combination may be effected when the subjects are taken on glass in the ordinary way. In the previous article, it will be remembered, we indicated, somewhat briefly, how this end might be attained by removing the film from the plate. At the same time, however, we pointed out that, in inexperienced hands, the method would be attended with some little risk of failure, arising from a tendency in the gelatinous films, when removed, to expand, and that often unequally in the different negatives.

The method now to be described is to reproduce the negative through the medium of a transparency. By this method of procedure we have the choice of two ways of effecting the combination. It can either be done in the transparencies or in the second negatives. Each plan, it may be explained, possesses certain advantages over the other. If the combination be made in the transparencies it involves the reproduced negative being made as a whole the same size as the finished picture. This may possibly necessitate working on a larger scale than that to which the operator is accustomed, while by the other plan the reproductions are all the same size as the originals. The latter method may therefore commend itself to some, but the former is the one which is capable of yielding the most satisfactory results, and, on the whole, with the least trouble. For when the combination transparency is once obtained, a single exposure secures the final negative; whereas, when it has

to be produced by different printing from separate transparencies there is the greater chance of their not being identical in density. Therefore, the former plan will be the one first described.

The first thing is to produce flexible transparencies from the different negatives. These are best made on stripping films by contact printing, the exposure being to artificial light on account of its uniformity. The exposure should be a very full one, so as to avoid forcing in the development. The developer may be any with which the operator is most familiar, and the different transparencies, it goes without saying, must be made of as nearly an equal density as it is possible.

In making transparencies for the reproduction of negatives the great fault with novices is under exposure and over development; hence the reproduction is too often lacking in detail, as well as being hard and crude in the lights. A good transparency for reproducing negatives should possess full detail in the very highest lights, even when viewed in a strong direct light. It should also be much denser than would be permissible in the case of lantern slides. Indeed, a transparency for our present purpose would be perfectly useless for lantern projection. When the pictures are fixed and washed they are stripped on to the gelatine skins in the ordinary manner.

In place of the stripping films, the carbon process, if the operator be familiar with its working, may be employed for the transparencies, the image being developed on glass and afterwards transferred to a film of gelatine. It matters not by what process the transparencies are made, so long as the quality is right and they are of a flexible character.

When the transparencies are stripped they are joined on a glass plate, in the same manner as that described for negatives in the previous article, which need not here be recapitulated. It is always difficult to successfully hide a join through the sky of a picture. Therefore, unless the clouds in the original negative be exceptionally good, it will be better to sacrifice them altogether and substitute others. In this case the sky should be masked out in the negatives, so that in the transparencies it shows as clear glass.

There are two ways by which the clouds can be introduced into the picture. They may either be put into the transparency or they may be introduced in the ultimate print by printing from a cloud negative. If they are introduced into the transparency—and this is undoubtedly the best plan, as then the clouds are secured in the final negative, so that double printing is afterwards obviated—they may be put in with delicate washes of colour on the back of the glass, or by stumping them in on the film with plumbago. No difficulty will be experienced here by any one who can use the brush or stump, for, as the lights and shades are as seen in nature, what is made to look well in the transparencies will look equally as well in the finished prints. The only thing to be avoided is making the clouds too pronounced. If requisite the shadows of the picture at this stage may be strengthened with plumbago or colour, or any imperfections may easily be remedied. The transparency being finished, the second negative is then made, like the transparency, by contact printing, but on a dry plate, artificial light again, by preference, being employed as the source of illumination, on account of its being more uniform than daylight. The exposure in this case should be full, though it should not be overdone. The development and after treatment of the negative does not, of course, differ from the ordinary method of working.

If, instead of making the combination in the transparencies, it be decided to make it in the reproduced negative, then the transparencies may just as well be made on dry plates, as, in any case, the reproduced negatives must be in the film form. In this case it will be useless to attempt to introduce the clouds at the transparency stage, as this would materially add to the difficulty of hiding the junctures in the finished negative. In this the sky may be blocked out, so that it prints quite white; the clouds can be introduced into the prints from a stock cloud negative. The joining manipulations, whether they be carried out in the transparencies or the reproduced negatives, are precisely the same as those given in the former article.

In the event of the transparencies or the second negative varying slightly in density, this may to some extent be ameliorated by coating the backs of the thinner one, or ones, with matt varnish or with mineral paper. It is manifest that when the combination is made with the transparencies there is far greater scope for remedying defects, as we have the chance of doing it at every stage; whereas, when it is made in the reproduced negative this opportunity is more circumscribed.

WE remind our readers that there is now open, free to all photographers, an exhibition of "one man's work" in the rooms of the Camera Club, the works in this instance being those of Mr. Joseph Gale. All should see this admirable collection, which they can do on application at the Club, Bedford-street, Strand.

WE are glad to see that still another Society has been formed in London, this time in Hackney. The meetings are to be held monthly during summer and fortnightly during winter. We wish the young Society all prosperity.

WHAT is a "nickel" prism? We had never heard of this term previously, but we have now come across it in the last number of the journal of the Photographic Society of Great Britain, which is considered to be a scientific journal. A prism implies something by which light is capable of being transmitted; but all the nickel we have seen is an opaque metal. From the context we would imagine the so-called nickel prism to be in reality a prism formed of that particular carbonate of lime known as Iceland Spar, which possesses the property of double refraction of light, and which, from a peculiar method of cutting the same, discovered by a long-since-deceased Glasgow *savant*, has since borne his name, and is very well known as the Nicol, or, as now commonly spelt, the Nicol prism.

WE have to thank Mr. T. C. Hepworth for a new term as applicable to a certain class of photographic portraits. In his *Camera* he says that those who are about to be photographed by flash light, and do not want to be mistaken for *Blue-ruinites*, should never look towards the flash, as it shows the eyes "in the shape of lazy, half-closed lids, which give rise to suspicions with regard to the temperance of the sitter." This is precisely the nature of the suspicions we and others entertained when inspecting four flash-light groups of four different photographic societies in our possession, all of which suggest "blue ruin," a suggestion intensified by the presence of various glasses on the table—glasses of a class not usually to be found among the appliances of a chemist's laboratory.

BEARING on the important subject of varnishes, a portion of a paper having no other connexion with photography, recently read before the Institution of Naval Architects, will yet be of special interest to photographers. Really a great portion of the paper might with advantage be read by them, for many points of contact between its subject matter and the varnishing of photographs arise in its course.

THE writer dealt with the various means of coating iron and steel ships with paint, varnish, or other anti-fouling compositions, and it is with regard to the second-named that the photographic interest arises when he describes its application and effect. The writer, Professor V. B. Lewes, states that "no varnish is impervious to gas or liquids." Here, at the outset, is a statement of the utmost importance to photographers, for it is generally thought that when once a protective coating is applied to a negative or print the action of noxious air is entirely prevented. But the explanation of his dictum at once tells us how the false impression has arisen. "We are apt to think," he says, "of a coating of varnish as being perfectly homogeneous, but, on examining it through a microscope, it is seen to be full of minute capillary tubes." The application of several coats of varnish tends to diminish this evil, as in many cases the holes in the first coat will not correspond with the holes in the second, and so each succeeding coat will tend to make the protective more and more impervious.

IT is not to be supposed that in consequence of these remarks photographers will in the future make a practice of double or treble varnishing their negatives, for, as we need not say, many gelatine plates are printed from without any varnishing at all; but where a large number of prints are required from the same negative it appears that Professor Lewes has given us a practical means of increasing the value of varnishing. This is no light matter. Every printer of experience knows the effect upon a negative when by accident, or in a shower of rain, water has gained access to a negative upon which a piece of silvered paper was pressed. Again, too, the practised printer knows that continuous printing from a negative at times results in the silver salt somehow finding its way to the film itself, whence it can never be perfectly eliminated, and it is now allowable to suppose that by using a thin varnish and coating the negative several times perfect immunity from silver stains may be expected.

IT is a matter of course nowadays that the aid of photography should be called in to assist in scientific investigations requiring accurate demonstration, but it sometimes happens that the demonstration itself requires explaining, and this has recently happened in the case of photographs of lightning flashes, in a number of which that have recently been exhibited are to be found two singular phenomena—a duplication of particular flashes and the appearance of what is termed a "dark flash." It is evident that a double flash might possibly be seen by the unaided eyes, but that if such a phenomenon as a dark flash were in existence the brilliant light of the ordinary flash would render its visual appreciation almost impossible.

THE double flash has been ingeniously explained as being possibly caused by the flash having been taken through a window, in which case it would be strange if a second or duplicate flash were not seen. Mr. Whipple, at the Physical Society, stated that even white chalk lines on a blackboard showed such duplication when taken through plate glass, and through ordinary "window glass." But the *English Mechanic* quotes a writer in the *Bayswater Chronicle* as "speaking from personal knowledge that the ribbon lightning photograph was taken in the open air, and not through a window." If this be so the explanation is as far off as ever.

IT would be deemed paradoxical to state that silver was insoluble in nitric acid, yet, strictly and exactly, the statement would appear to be true. At a recent meeting of the Chemical Society, in the course of a discussion upon the rate of solution of metals in acids, the writer stated that he had had occasion to verify Dr. Russell's observation that silver is not dissolved by nitric acid free from nitrous acid. Of course the action once started this acid would be formed, and then the usually understood dissolution would progress. The point is to cause the initial action to be called into play. We need scarcely say that the discussion has not a practical bearing upon such operations as making nitrate of silver, for in the first case perfectly pure silver

would never be employed, an electrolytic action would be set up to cause solution in any other sort. Secondly, any acid likely to be used for the purpose would contain nitrous acid in some small degree, and hence cause the action to be started, which is all that is needed to ensure total dissolution in the presence of a sufficiency of dilute nitric acid.

PHOTOGRAPHIC CONVENTION OF THE UNITED KINGDOM, 1889.

ARRANGEMENTS for the Photographic Convention of the United Kingdom for the present year are fast approaching completion. The Great St. James's Hall, Piccadilly, has been taken for the week of Convention in August, some influential patronage from the worlds of science and art secured—the list including such names as Lord Rayleigh, the Archbishop of York, Sir J. D. Linton, Dr. William Huggins, Mr. Vicat Cole, Professor Dewar, &c.; and plans are practically settled for the exhibition of apparatus and pictures in the splendid hall which has been secured. Manufacturers and dealers will probably soon have before them conditions for the exhibition of their goods, and it has been determined to make no charge for pictures not exhibited *bona fide* for commercial purposes.

A new, and probably welcome, feature is to be an exhibition of coloured pictures from or on photographic bases, but for evident reasons arrangements must be made to prevent the colour work from marring the effect of plain photographic prints. The exhibition of photographs will, it is expected, be of high quality rather than of large extent, but on account of the *prestige*, the centrality, and the ease of access of the hall, a "run" may be expected on space for exhibits of apparatus. It is also a part of the project to get together a collection of material marking historically the eras of photography, and inventors will find encouragement and facility for displaying any outcome of their genius, whether new or old.

The optical lantern will be used on a gigantic scale, papers read by the highest authorities, and a varied series of entertainments will mark the Convention week.

ECHOES.

REFERRING to Mr. J. A. Forrest's remarks on *Ground Glass Sensitive Plates*, I think they are mixed up with a little ambiguity. For instance, he speaks of the "tooth" the ground surface gives for retouching, the increased hold it presents to the emulsion, and incidentally the larger quantity of the latter the glass will hold. Finally, he mentions the "non-halative" quality of such plates.

Now, though it seems to me that so far as the emulsion is affected by the ground glass it is of course obvious that it must be applied directly to the corroded surface, but as regards retouching and halation I am left in doubt as to which side is intended to be used, or perhaps I should say that while Mr. Forrest seems to intend that the ground side is to be coated, I fail to see how it can under such circumstances have any beneficial effect.

For instance, with reference to retouching, the coat of emulsion itself will mask or destroy any tooth that the corrosion of the glass surface may present, for it is impossible to believe that the thick layer of bromised gelatine can adapt itself so closely to the minute grain of the etched plate as to show any roughness or "tooth" on its own surface; but if the polished side of the glass is to be coated, then the back remains available for the pencil. Again, in the case of halation it is reflection from the *back* surface of the glass plate that causes the trouble, and not the front or film-bearing side; consequently, in coating the corroded or roughed surface with emulsion, though the light passing through the film may be very slightly diffused before reaching the back of the glass, it is not to any appreciable degree deprived of its tendency to produce halation when the necessary conditions prevail. On the other hand, if the plain side be coated the light undergoes diffusion on leaving the back surface, but even then the beneficial action must be inferior to that produced by total absorption.

By the way, too, Mr. Forrest is rather ambiguous in what he says about fluoric acid and chloride of ammonium. Thus he says, "This acid is bought in druggists' shops and sold in lump." Which? I

never heard of "lump" fluoric acid, and I scarcely think even a country druggist would class sal ammoniac amongst the "acids." But Mr. Forrest continues, "as it is gradually added to the fluoric acid," so that it would really seem as if the "chloride of ammonia" is the acid intended. Finally, he says "it has become known as 'white acid.'" What? Sal ammoniac alone or the mixture with fluoric acid?

The "wrinkle" regarding the addition is, however, a valuable one to those who wish to avail themselves of this somewhat unpleasant method of obscuring glass. I remember trying the method many years ago, but the fault was that neither the liquid acid nor its vapour would give me sufficient grain, or rather opacity, to be of much use, either for focussing purposes or for backing transparencies. The result was, in fact, very similar to an oiled focussing screen.

Once again we are treated to a report of the invention of an automatic portrait-taking machine, by means of which a victim—I mean person—having of course "put a penny in the slot, may seat himself in a chair, and by pressing a button be photographed instantaneously." It is interesting to know that "the objective is placed in front of the chair," not behind it be it noted, and that "the portrait is delivered a few minutes after sitting." But Messrs. Carquero and Guillaumont might further inform us what arrangement the machine is prepared to make in cases of downright failure, and whether in the event of the "expression" not being entirely satisfactory any reduction in price is made for a "re-sit?"

The method of photo-engraving on wood given in last week's *Foreign Notes and News*, on the authority of *Les Inventions Nouvelles*, is interesting so far as the details go, but scarcely sufficiently clear. In the first place, What is the particular function of the carbonate of copper with which the pores of the wood-block are impregnated, and what is the effect upon the wood itself of the process by which that end is effected, namely, *boiling* in alternate solutions of sulphate of copper and carbonate of soda? I was under the impression that wood engravers endeavoured to keep their blocks as free from contact with water as possible, but boiling is an operation they would, I imagine, religiously shun. The coating of "sensitive gelatine" on which the subject is "photographed" is, I suppose, simply bichromated, though the account reads as if the exposure was made in the camera. After developing the image and "inking up" the impression with an asphaltic varnish-ink, we are told that the block is immersed for an hour each in concentrated nitric and sulphuric acids, by which means "the wood is eaten away wherever it is left unprotected by the varnish." So I should think; but what about the sharpness of the lines and the condition of the wood with which the acids have been in contact without dissolving? It does not seem to me, on the face of the description, that such blocks would have a very long life.

A question arose at the London and Provincial Association as to the possibility of toning with acetate of lead and hypo. From the report I cannot say what were the details of the method suggested, but I can say that the colour of a silver print can be changed under conditions which are rather those of decomposition over the whole surface than of a properly so-called toning process, and yet without the production of the unsightly results to be expected from such a method.

If a silver print, either untuned or toned, be fixed in hypo, and after a partial washing be immersed in acetate of lead, a decided change in the colour of the image will be apparent, more so in the case of an otherwise untuned proof than when gold has been used. The brick red of the untuned print is changed to a sepia brown, while the purple or black gold tone is more or less modified by the admixture of brown.

A similar, though less powerful, result is produced by using a strong solution of alum instead of the lead salt, and, so far as I am aware, from my own experiments, the reaction, in both cases, requires the presence of soluble silver salts, *g.*, silver hyposulphite or the double salt of silver and sodium. This is decomposed by either acetate of lead or alum with formation of sulphide of silver, and other forms of sulphur, including of course, in the case of lead acetate, the sulphide of that metal. A *slightly* washed print, after removal from the hypo, may be thus toned, but I never succeeded in producing any appreciable change when the proof had been thoroughly freed from silver hyposulphite—that is to say, a perfectly washed print, reim-

mersed in *fresh* hypo before treatment with the "toning" solution, failed to give the same result.

It is curious, seeing that the change arises from the decomposition of a substance with which the print is uniformly pervaded, that the whites and lighter tints should not show an even greater change of colour than the shadows, since the very slightest deposition of silver or lead sulphide would be more palpable on an expanse of white paper than where a deposit of silver already existed. But such is not the case, and I have seen prints that upon removal from the hypo have received a mere "rinse" and after treatment with the solutions named have presented a really respectable appearance. How long they might continue in that condition I am not prepared to say, but I fear not long.

JENKS.

THE WHOLE ART OF PHOTOGRAPHY IN A SERIES OF EASY PROGRESSIVE LESSONS.

CHAPTER II.—CONCERNING LENSES.

THIS chapter, it may at once be said, is not to be devoted to the nature and properties of lenses (which will remain for subsequent treatment), but will prove only as a stepping-stone to the beginner who knows as yet little, if anything, of photography, yet is desirous of having a general idea of the tools with which he is to work.

For the present it will be enough to say that lenses are either single or compound, and these in turn may be either simple or achromatic. A lens is usually termed single when only one is employed, and this being mounted at one end of a short tube with a diaphragm at the other end constitutes a landscape lens, so named because of its being specially suitable for landscapes or for outdoor groups in contradistinction to one which has a lens at each end of the tube with a diaphragm midway between, and which is more suitable for architecture or copying, being orthographic or rectilinear.

A landscape lens will cover the plate both flatly and brightly, but if the subject were a house there would be a slight curvature in such lines as fell near the margin of the plate. By employing two lenses in the tube the distortion of the straight lines caused by the one lens would be counterbalanced by the opposite distortion of the other, for while every single lens distorts in itself it depends upon the relation of the lens to the diaphragm whether it shall do so in one direction or the other, and with two lenses and a diaphragm between we have the opposing conditions balanced, the result being rectilinearity.

This is the case whether the lenses be achromatic or merely simple lenses of the spectacle-glass nature.

An achromatic lens brings the rays of every colour to one general focal point, the working or chemical focus coinciding with the focus as seen by the eye, or visual focus as it is termed; but if simple or non-achromatic lenses are employed the focussing screen of ground glass would have to be a *little* farther away from the lens than the plane on which the sensitive plate is placed in order to obtain the sharpest results. The precise distance is one-fortieth of the focus.

The single achromatic or landscape lens is a most satisfactory instrument for a beginner in photography, and one with which he will experience much satisfaction in photographing such views and scenes as will engage his attention for a considerable period. The photographic aspirant need not here conclude that it may be better for him to purchase at once a lens which possesses far higher virtues than those to be found in the single achromatic, because not only is this a safe instrument with which to commence his operations, but it is one which he will never care to part with in the hereafter of a more extended experience when he shall have considerably added to his optical supplies. Let him also bear in mind that some of the finest landscapes the world has ever seen have been produced by this lens.

The beginner, too, may be troubled to know the meaning of the, to him, cabalistic terms by which the intensity of a lens as produced by its diaphragms is designated, such as $f-4$, $f-8$, $f-20$, &c. This will now be explained in terms sufficiently simple as to be understood by all. Suppose that a lens is said to have been working at $f-6$, it means that the diaphragm has an aperture one-sixth of the focus of the lens. If the focus be six inches, then would an aperture in the diaphragm be one inch in order to represent $f-6$, and this ratio holds good no matter what the focus of the lens may be, whether six, nine, twelve,

or twenty inches, $f-6$ would simply be a working aperture (in the diaphragm or stop) equalling a sixth of the focus. So with other figures. The lower the number the greater will be the intensity of the light transmitted through the lens, and therefore the greater the rapidity of its action. It is not the *actual* diameter of the aperture that determines the rapidity of a lens, but the diameter as compared with its focus.

The most rapid of all the lenses that have yet been introduced is the portrait combination. This is made with various degrees of rapidity. Some have the unusually great aperture of $f-2.5$, and are, designated "baby" lenses, from their suitability for taking instantaneous pictures of babies in even a dull light. High-class *carte* or cabinet lenses are constructed with an aperture of $f-3$; ordinary portrait lenses work at $f-4$, and a slower class of portrait lens, to which such trade terms as "D," or "Universal," or "Group" lenses have been applied, equal $f-6$. In all of the above the back combination is separated, an air space being between its two components.

The cemented "rapid" class of lenses come next in point of rapidity. The most rapid of these, of the Group or Euryscope order, have apertures equal to $f-6$, although some of the smallest are $f-5.5$. The average "rapid" objective of this class is $f-8$. This is known by so many trade names that to designate them would be impossible. Next in order of rapidity follow the "portable" lenses belonging to the same class, whose aperture usually equals $f-16$, although some are a little more rapid than this. Last of all come those intended to embrace a very wide angle of view, for the greater the angle intended to be included the smaller must be the working aperture.

Some single lenses are now made to work with so large an aperture as $f-8$, but this is mainly for portraits or groups. For landscapes it is not advisable to employ them with such intensity, but to stop them well down in order to get depth and good covering power.

"GONE BAD."

How constantly do we hear this expression applied to anything and everything, from a potato to a man, from a piece of gelatine to a finished photograph! Of all the multitude of substances with which the modern photographer has to deal I think we would find some difficulty in picking out a dozen which are not liable at one time or another to deteriorate. In the main there are two great causes for the "going bad" of both men and materials, and these are dirt and neglect. Certain men there are here and there in this world who *will* keep their iodine in paper parcels, their pyro in jelly-cans, and their gelatine in the sink, for these people I do not write, but rather for that well-meaning "brother of the dirty fingers" who finds the obstinate moral obliquity of his materials a source of serious expenditure, both of money and temper. For this brother in adversity the chemist may draw certain valuable or curious facts from his experience. Firstly, then, to take the case of solutions; these are all, more or less, liable to evaporate. How may this be prevented? If a solution has to be kept for a long time absolutely unchanged there is really no certain method whereby this may be accomplished, except by sealing the vessel containing the liquid with the blowpipe. Narrow-necked flasks and tubes of all sorts may be treated in this way without much difficulty by any one who has even a little experience of glass working, and who possesses a gas blowpipe. This process is actually used now by certain dealers who send out ready-made developer in sealed tubes; and chloride of gold is always packed in this way. As using the contents of a sealed flask or tube involves destroying the vessel, this method, although the only absolutely trustworthy one, is too expensive and troublesome to be generally employed. It might often be used with advantage where unstable substances have to be carried a very long distance before use, the tubes being opened and their contents transferred to bottles when necessary.

All this however, so far as the majority of photographers are concerned, is not practical politics. With them the question reduces itself to, How may the contents of bottles be preserved unchanged? To begin with then; do you know how to tie down a cork or stopper? I will venture to say that nine out of ten do not. A knot, however simple, cannot be made intelligible by description without a number of diagrams, so for the acquirement of this art it is best to see the thing done by a druggist or other experienced person. Stoppers of bottles containing strong ammonia or other should always be tied down; but stoppers are liable to stick, an event which often leads to the sacrifice of both bottle and contents. It is said that this may be prevented by covering the stopper with a thin film of paraffin wax. Certain

substances should never be kept in stoppered bottles, because they invariably cause the stoppers to stick sooner or later. These are for the most part substances which are acted on by the air, such as caustic potash or soda, carbonate of potash or soda, ferrous sulphate, water glass, &c. For these indiarubber corks are the best, common corks being very quickly attacked by the caustic substances. It is often very difficult to get a cork which fits really air tight, but this may usually be done in the following manner:—Select a cork of good sound appearance, considerably too large for the bottle to be fitted, and boil it in water for a few minutes; it will become so soft that it can easily be forced into its place, and after it is cold it will retain the exact form of the bottle neck. A test tube or thin flask is very apt to break if corked in this way. In order to keep ammonia solution of approximately known strength, a very simple plan is to dilute the '88 ammonia as bought with an equal bulk of water, and then always use twice the quantity stated in mixtures. A few liquids may be prevented from evaporating by a layer of oil, but this, of course, does not apply either to liquids which might dissolve the oil, such as alcohol and ether, or to those which might act chemically on it, like the caustic alkalis; farther, as few, if any, oils can be said to be absolutely insoluble in water, the method is always objectionable. A few solutions, instead of evaporating and becoming stronger, decompose on keeping and so become weaker. Potassium permanganate solution gives off oxygen and becomes weaker after keeping for some months.

So much then for liquids which lose some part of their substance on keeping. Let us consider now the more difficult subject of preventing the addition of oxygen or water from the air to materials which have an attraction for these substances. The first thing the photographer will naturally think of in this connexion is pyrogallic acid. I have lately performed a number of experiments on the preservation of pyrogallic solutions, a report of which I hope to lay before the readers of the JOURNAL at an early date.

Substances which are deliquescent must, of course, be kept in bottles as nearly air tight as possible, but even this may not always suffice. A few bodies which are extremely deliquescent, sulphuric acid and zinc chloride for instance, attract moisture through the best ground stoppers. At first sight this seems impossible, but it happens in this way. A little, let us say of the zinc chloride, sticks in the neck of the bottle when it is exposed to the air, and soon absorbs so much water as to turn liquid; we then have a film of liquid exposed on the one hand to the absolutely dry air inside the bottle, and on the other to the moisture of the atmosphere. The solution becomes very concentrated on one side and weak on the other, and diffusion tends to mix the whole, so that water is always gradually carried in and evaporates from the inside of the neck of the bottle. This process is naturally a slow one, but I have often been surprised at the amount of water which could pass through a good stopper in a few months. All this explanation would be quite out of place here did it not point out the remedy, which is to clean the stopper and apply a trace of grease, or, if that be objectionable, to wax it round the top with a hot wire. All solutions of ferrous salts (and the solids in a less degree) are liable to spoil by absorbing oxygen. As the substances are cheap it is usually best to make them up as they are wanted; but old solutions may be reduced by boiling with clean iron or zinc and filtering. A solution of a ferrous salt containing no ferric should give a pure white precipitate with potassium ferrocyanide. Ferrous ammonium sulphate has almost exactly the same reducing qualities as ferrous sulphate, and keeps much better both as crystals and as solution. Solutions of nitrate of silver often become black by keeping, this is entirely due to the use of impure materials or dirty bottles; pure silver nitrate dissolved in distilled water should remain clear indefinitely, either in daylight or in the dark, if kept in a well-stoppered bottle. Traces of organic matter, such as may enter from the air, will cause a black precipitate. Somewhere I have seen the statement that there is a micro-organism or germ which inhabits the surface of crystals of nitrate of silver. This, however, cannot be the case, because the protoplasm of the creature would be immediately destroyed by contact with the caustic.

Although "germs" certainly cannot live on nitrate of silver, the things they can live and thrive upon are many and various. They can flourish upon the most hopelessly unfertile soil. Be it remembered, however, that no organism can live long or grow at all upon a surface which is dry; hence the necessity for keeping plates and solutions in dry places. Speaking generally, most organic substances, and some inorganic, are liable to "go bad" by putrefaction or moulding. The following solutions I have found to mould or ferment on keeping:—Potassium nitrate (even saturated solutions), sodium sulphate (very slowly), tartaric and citric acid, and all tartrates, citrates, or acetates, except those of silver. The change is always retarded and often prevented entirely in concentrated solu-

tions. Liquids containing sugar, starch, gelatine, albumen, or gum, all spoil so rapidly that antiseptics have to be used if they are to be kept more than a few days. The choice of antiseptics open to the photographer is not large, as he must avoid like the plague anything which could conceivably affect the permanency of his photographs. He would be a rash man who would assert dogmatically that any treatment which had not been tried for at least twenty years would not affect silver prints, but so far as human foresight can go alcohol and eucalyptus oil must be safe preservatives for mountants, and the latter is a more effective antiseptic than carbolic acid.

Litmus solution occupies a unique position, in that it must be kept in open vessels to prevent its loss of colour. Old litmus, which has grown brown or nearly colourless with keeping, may be restored to its original brilliancy by leaving it for a few days in an open flat dish.

All these putrefactive changes may be combated, either by the use of antiseptics or preservatives, or by sterilising. The latter process might be resorted to by photographers more frequently than it is for the purpose of preserving gelatine solutions, and such preparations which stand boiling, but are liable to be destroyed by addition of an antiseptic. Sterilisation is a very simple process, and is performed by boiling the liquid and then excluding all but filtered air from contact with its surface; in other words, by plugging the flask or bottle tightly with clean cotton wool. This allows air or steam to pass through freely, but stops all germs of fermentation or moulds. Even the most highly putrescible liquids, if properly sterilised, may be kept indefinitely.

C. I. BURTON.

AN EASY AND ECONOMICAL METHOD OF MAKING LANTERN PLATES.—IV.

AFTER the emulsion has been melted and made up to eight ounces it is ready for being filtered.

A great many ingenious and complicated methods of doing this have been proposed, but I prefer to do anything in as simple a manner as possible, so I always use a common glass paraffin lamp chimney, the sort with a small outside rim round the bottom edge; they cost about 2d. each. Over the bottom I tie a fine linen handkerchief (six or eight thicknesses), and then pour the melted emulsion into the glass and give a good hard blow in at the top and the emulsion goes through splendidly.

The emulsion is now ready for coating the plates. We shall require a level surface for the plates to lay upon while the gelatine is setting; if one has not a table or shelf perfectly level, a drawing board, levelled with the aid of three wedges, or, what I prefer, three screws, will do very well. Two of the screws are screwed about half an inch through the wood near the two corners at one end of the board, the third screw passes through the wood midway between the two opposite corners. The screws act as three feet for the board, and from their positions form the three points of a triangle.

A level is placed midway between the two corner screws, and they are screwed in or out until the board is level. The level is then put lengthways along the board, and the third screw is raised or lowered as required. File off the sharp points of the screws.

Looking round a glass cutter's shop some years ago, on his scrap heap I saw a number of strips of plate glass two or three inches wide. These were just what I wanted, and I had them cut up into sixteen and twenty inch lengths. They are much better to lay the coated plates upon than a large flat surface; besides, sometimes a little of the emulsion will run over the edge of the plate and cause it to stick to the levelling slab, but it is very easy to detach it if these strips of glass are used, but it is often an awkward job if one uses a large slab of slate or plate glass to get a plate off it if it sticks.

I lay these strips of glass on my level table or board, and as the plates are coated with the emulsion they are placed upon them for it to thoroughly set, the plates are then put in the racks ready to go into the drying box.

The best receptacle for holding the emulsion when coating plates is, I think, an ordinary invalid cup (with the handle at the side), because any air bubbles formed when pouring the surplus emulsion back remain on the surface, and the emulsion passing down the spout is drawn from beneath. With care, however, a bottle or measure can be used to hold it.

As to the temperature of the emulsion when coating, I prefer it to be as cool as possible, while at the same time flowing readily over the plate. If it is too warm it does not flow in such an even wave over the plate, and is apt to run over the edges. But with a very little practice one soon learns the right temperature, &c., for plate coating.

Old collodion workers, or, indeed, any one who can varnish a

negative, will find no difficulty in coating the plates. Breathe on the surface of the glass, pour a pool of emulsion on the centre of the plate, flow it to the further corners, then to the left hand nearer corner, and finally to the right hand corner, from whence the surplus is poured back into the cup. The plate is gently rocked for two or three seconds, and then carefully placed on one of the glass slips for the emulsion to set, and another plate is coated in a similar manner.

Rather less than a drachm of emulsion will be sufficient for each plate, and it is as well to check off the number of plates coated with the amount of emulsion used every now and then (allowing about nine plates to the ounce of emulsion), because as the latter cools more clings to the surface of the plate, and it is necessary to drain it a little more.

It saves a great amount of time in coating if one can get a friend to help by taking the plates as they are coated and laying them on the glass strips. With his assistance one can easily coat a gross of small plates in an hour.

One of the best formulæ for the development of these plates which I have found so far is the following:—

No. 1.

Hydroquinone	15 grains.
Sulphite of soda	75 "
Water	5 ounces.

No. 2.

Carbonate of potash	90 grains.
Water	5 ounces.

No. 3.

10 per cent. solution of bromide of potassium.

Use equal parts of Nos. 1 and 2, and add two or three minims of No. 3. With some samples of gelatine, however, no bromide restrainer will be required.

HERBERT S. STANNES.

A PHANTOM IN A PHOTOGRAPH.

THE venerable and usually quiet town of Ipswich is at present in a ferment, and all through the appearance of a figure in a photographic negative of a river scene, no such figure having been seen by either of the two gentlemen whose cameras were busy in depicting it. We learn the story from the *East Anglian Daily Times*, from whose columns we have condensed what follows.

It appears that on Saturday last the gentlemen referred to (Mr. R. Cash, master of the Shirehall Board School, and Mr. E. H. Pringle, solicitor) were taking photographs of the Gipping. Both the gentlemen mentioned are members of the Amateur Photographic Society; Mr. Cash was the operator, and the light being favourable, he obtained some capital views at various points on the riverside. One of the scenes selected, depicted from the lock gates, showed a reach of the river in the foreground, with trees overshadowing the bank on one side and a group of boys fishing on the other; the end of the Steam Laundry was in the middle distance, and far beyond were the spire of the Presbyterian church and the roofs of other buildings. The photograph was taken on an ordinary dry plate by the instantaneous process. Neither Mr. Cash nor his companion saw anything unusual or mysterious at the time. It was about four o'clock in the afternoon, and the sun was shining brightly upon the surface of the water from behind the camera.

In the evening, however, while developing this particular plate—Mr. Pringle being still in his company—he was perfectly astounded by an appearance which he had never seen when taking the photograph, and for which he could in no way account. On completing the development there was plainly revealed, in the foreground of the picture, the figure of a woman, apparently floating upright in the water, as it is declared that drowned bodies sometimes will after immersion for a certain length of time. "I cannot in the least explain how it got there," said Mr. Cash, when interviewed on Monday, "but here is the negative, and you can see for yourself." And, says our Ipswich contemporary, it can only be said that the woman is unmistakably shown. It is no shadowy likeness difficult to detect, nor does it require pointing out before the lines can be traced, as with the puzzle pictures so commonly seen. The face and head are clearly outlined; the arms are hanging straight by the side of the body, which is clad in ordinary female attire, and is visible to the waist; and the portrait generally appears to be that of a tall and comely young woman. There is nothing repulsive in the photograph, although it looks weird and ghost-like.

Unable to account for the apparition, Mr. Cash communicated with the borough police, one of whom was so struck with the reality of the picture that he at first imagined it to resemble some woman in the town,

and inquired whether she had lately been heard of. Next morning the river was dragged at this particular spot, but no body was found; and so far, therefore, the climax of the narrative is happily left wanting.

It has been suggested that there was a defect in the film, and the hypothesis might be entertained if the figure were not so well-defined; but it is hard, if not impossible, to believe that it is the mere result of accident—that the shape should be so exactly that of a woman, or that it should fall in the picture at the precise spot where it is seen. Another theory is that the plate had been used before, and that the old negative was not completely cleaned off. In reply to this, however, it is said that the plate was new, and that, as a matter of fact, it is cheaper to issue fresh plates than to reprepare old ones. It is altogether a perplexing mystery. There is the girl in the photograph, and, like the fly in amber, nobody knows how she got there. About the good faith of the operators in the matter there can be no question, and it is certainly one of the oddest things ever chronicled that a river should be dragged all on account of a phantom in a photograph.

CAMERA CLUB CONFERENCE PAPERS.

IV.

PHOTOGRAPHY AND THE LAW OF ERROR.

By CAPTAIN ARNEY, C.B., R.E., F.R.S.

THIS Conference, I hope, will excuse such an uncanny title as that which I have chosen. It looks odd, to say the least, seemingly indicating that photography is subject to errors of some description. I am not going to enter into any optical errors to which it is liable, but only to its inability to render truthfully the gradations of black and white. A question which I have often asked myself is this: "In a negative or in a print, do the values in density of deposit, that is, in the translucency of the former and in the blackness of the latter, have any relation to the value in intensity of the light acting to produce such density or blackness?"

This question, as I have said, I have very often asked myself, as my writings will show; but it is only quite recently that I have been able to answer the question satisfactorily to myself, and I hope it will appear equally satisfactory to the meeting.

If an initial impact of light has to be given in order that any action may be visible on a negative or print on development, we may suppose, after such an impact, that equal increments of intensity in light will give equal increments of action on the sensitive salt; but it by no means follows that the density of deposit will proceed by equal increments. As an example, if we take an intensity of light which we may represent by 1, and another intensity of light which we may represent by 2, and allow them to act on different parts of the same plate, it by no means follows that on development the opacity caused by the latter will be double that caused by the former. We may look at it in this way: If we have " n " circular discs of very thin metallic silver, and place them at random on an area of a given size, it may be, or may not be, that some will overlap others; but the chances are much greater that, if we have $2n$ of these discs, and scatter them at random on the same area, some will overlap others. Suppose in the case of the n discs none overlapped, but that in the case of the $2n$ discs some did, and if the area of each disc was a , and the area of the surface on which they were scattered was A , then in the first case the transparency of the surfaces to light would be measured by $(A - na)$, and in the second, $A - (2n - 2nk) = A - 2n(a - k)$, where k is the amount of average overlap of the discs. Evidently, then, the transparency of the last area would not be twice that of the former. In the same manner it can be argued that by increasing the number of particles to 3, 4, &c., " n ," the transparency would not be proportional to the number of particles scattered. This is exactly what occurs when light acts on a film. The number of particles of deposited silver in a given area are presumably proportional to the intensity of the light acting, but they are in a sense scattered at random over that area, and hence some overlap, and the overlapping increases as the number of particles increases. If this were not so we ought to have an intensity of light in which absolute opacity is introduced after a certain exposure, which we know is not the case.

Were it so in a Spurge's sensitometer, in which the light admitted to each chamber increases 2^2 , we ought, if we know the size of a particle, to be able to calculate the curve of descent. This can be readily done, for if we measured the transparency of the part of the plate where the intensity of the light was known, then that would give us a measure of the areas of the particles deposited, and we ought to be able to calculate the transparency for any other intensity of light. Thus, on a sensitometer plate, if the smallest hole gave a transparency to light of $\frac{1}{16}$ of the original light falling on it, then we should know that the silver deposit was $\frac{1}{16}$ of the area on which it was scattered. At the fourth smallest hole, where the light acting is doubled, the silver would occupy $\frac{1}{8}$ of the area, and the transparency would be $\frac{1}{8}$; at the seventh hole it would be $\frac{1}{4}$, and the transparency $\frac{1}{4}$; similarly, the tenth hole would give $\frac{5}{16}$, the thirteenth $\frac{3}{8}$, the sixteenth $\frac{1}{2}$, the nineteenth $\frac{9}{16}$ of transparency, while the twenty-second would cause total opacity of deposit.

Now, from absolute measurement we know that such is not the case; the curve which a developed plate exposed in the sensitometer takes is very different, as the diagrams show. The curve which the transparency takes is identical with the curve of error of observation, taking for abscissa the number of the holes and not their area. I may refer you to Sir G. Airy's book on the *Theory of Errors*, and there you will find that the probability of an observation being at a certain distance from the truth is expressed by the formula $A' = A e^{-kx^2}$ where A' is the probability of error and x the distance from the truth.

I should like here to give the measurements of the apertures of a sensitometer made on Spurge's plan, in order to show the accuracy which is attainable by it. The holes were measured by a micrometer made by Hilger, which is capable of measuring to $\frac{1}{100000}$ of an inch. The following measures were made in $\frac{1}{100000}$ of an inch. The largest hole is indicated as having the highest number; the holes diminish in area by $\frac{1}{23}$

HOLE No.	THEORETICAL.		MEASURED.	
	Diameter: ten thousandths.	Area.	Diameter: ten thousandths.	Area.

3	194	2.9	202	3.2
2	181	2.5	179	2.5
1	158	2.0	160	2.0

The boring of the holes will be seen to be very accurate, and the deviation from what was desired is as small as can be expected. In the very small holes the percentage of error is much larger than in the large ones, which might be anticipated.

(To be concluded.)

PROJECTING LIFE-LIKE MOTIONS.

THE popularity of the table Zoetrope and kindred instruments was sufficiently great when the optical lantern rose (by leaps and bounds) in public appreciation for its principle to be applied to various apparatus capable of projecting its phenomena on the screen; and among the most successful of these may be mentioned the *Lantern Zoetrope*, or wheel of life, and Beale's *Choreutroscope*. The best of the former is the well-known mahogany slide with brass fittings and interchanging discs of glass, having photographic designs of such subjects as "The Skater," "The Bottle lamp," "Fishes Swimming," and "The Giant's Ladder." These are very effective, but being in black and white, and only illuminated when on the screen by about one-eighth of the light employed in the lantern (because a metal disc has to revolve rapidly in front of the design in order to produce the effect of motion, and this disc has only a small section cut out of it for the light to pass through), it only answered for very powerfully lighted lanterns.

The Beale's *Choreutroscope* permits of either coloured or photographic pictures being rapidly shown in succession, so that by persistence of vision the object apparently moves on the screen. The original, made by Mr. Beale, and used at the Royal Polytechnic Institution, had the designs on a large circular disc of glass, and the present commercial lantern *Choreutroscope* has a long slide with a number of figures on, which, by the movement of a cam and shutter, momentarily obscures

one picture and advances or retires the slide one space, so that a different aspect of the same figure is shown (with normal illumination) and apparent motion conveyed. The *Praxinoscope* is a development of the wheel of life, and has the advantage of showing a series of pictures by reflection from mirrors instead of through slits in the wheel (as in the original). This was adapted by the French maker for lantern projection, but owing to the want of care with which the mechanical part was made, notwithstanding that a comparatively high price was charged for it, the demand, at least in England, was very small. The designs were painted on pieces of glass taped together, so that when placed in the wheel for revolving they would make a circle. Some modification of this apparatus should be scientifically and commercially successful if well made at a moderate price.

It has been left for Mr. Eadward Muybridge, of the University of Pennsylvania, to perfect an apparatus for not only photographing the consecutive phases of animal and other movements, but also for reproducing them on the lantern screen. The projection apparatus he calls the *Zoopraxinoscope*. It is an enlarged Zoetrope, as far as it contains a circular disc with the designs on, and a metal disc with the slits in, but it is necessarily far more substantially constructed, for the disc is about eighteen inches diameter, and in order that varying rates of speed can be obtained it has driving wheels and gear for rapid or slow rotation. It will be understood that, as the large disc of glass with the designs on has to rotate vertically in front of the lantern condenser, a special form of apparatus has to be made, and so the lantern body containing the limelight jet and condenser is supported on brass pillars to the necessary height, and the objective or front lens is carried on an arm or elbow from the front of body, so as to be at the right distance from the pictures on the disc to focus them on the screen. Mr. Muybridge has some hundred or more photographs of animals, birds, children, &c., in motion, and for each a special metal disc is required, or rather the metal disc must have slits to the same number as the subjects or objects on the slide if they are to go through their motions in a *fixed* position on the screen, or one more if to move forward, and one less if to move backward on the screen. The reason of this is not easily explained, but certainly progressive motion is obtained by having one more slit in the metal plates than designs on the glass discs.

The illustrations shown by Mr. Muybridge during his lecture at the Royal Institution settle many points in doubt among sportsmen as to the action of a horse when trotting, and among others prove conclusively that the horse at one period of each pace has all four feet off the ground. It will be of interest to state here that, in some of the series of photographs taken, the exposure of each picture was not more than one five-thousandth part of a second. G. R. BAKER.

Our Editorial Table.

THE PERFECTION DARK ROOM CANDLE LAMP.

BENHAM & FROUD, Limited.

THE mere announcement of the fact of this candle lamp being the inception of such a veteran and ingenious photographer as Mr. Frank Haes will prove sufficient to arrest attention.

We may state that the "Perfection" is a candle placed in the focus of a parabolic reflector, and that the position of the flame is always stationary. This position it has in virtue of a spiral spring, common to almost all such candles. As a lamp—that is, taken as a whole—it is elegant, and can grace as well the drawing-room table as the bench of the dark room. Contrived so as to have the most perfect ventilation, this is secured without any leakage of light: indeed, in the matter of combustion, several very ingenious contrivances have been imported into the "Perfection."

As will be seen from the illustration, the parabola points downwards, so as to direct the light upon the plate instead of in the face of the operator, as many do, and this suggests its applicability as a reading lamp for lantern lectures. The body is faced with a disc of non-actinic glass, neither ruby nor orange-coloured, but a species of "cross" between the two. When used for isochromatic plates these are held to one side, and out of the direct beam of light. The stand being telescopic, the light may be raised or lowered as regards its

height from the table. So perfect is the combustion that the flame (from a specially prepared candle) gives no smoke, and, as we have said, not a vestige of light is allowed to leak out except what passes through the front. The coloured glass can be removed without trouble, thus giving a beam of white light.

Between Mr. Haes, the designer, and Messrs. Benham & Froud, Chandos-street, W.C., the makers, they have produced a lamp at once elegant and most effective.

IMPROVEMENTS IN THE MODES AND MEANS OR APPARATUS FOR TAKING AND PRODUCING PHOTOGRAPHS, AND IN APPLIANCES CONNECTED THEREWITH.

No. 5140. JAMES HINES, Dunedin Lodge, Lenzie, Dunbartonshire; EDWARD HOWELL, Inglebank, Lenzie; and ALFRED HOWELL, Ingleisle, Pollokshields, Renfrewshire.—*April 6, 1888.*

This invention has reference to and comprises new or improved constructions, or arrangements and combinations, of the parts of automatic spring or weight-moved mechanism within a dark close box-stand, all self-contained or portable, and for the novel and interesting purpose or object of automatically taking the photographic likeness or miniature portrait of any person on a small prepared plate, card, or other equivalent, and then delivering it to the individuals by their merely putting a certain number of copper coins (as, say, three pence) into a slit conveniently formed and placed in the front case, and then turning or otherwise slightly moving a few handles placed outside in front a short time or number of seconds after each other, according to simple instructions printed at the side of each handle (or it might be only one handle or lever), a time-piece, with pointer indicating seconds, being also fitted in front for the purpose. These automatic machines for enabling any person (unskilled in the art) to take and receive delivery of a photographic miniature in a few seconds or minutes are devised for the purpose of being placed at railway and steam-boat stations, public markets, parks, gardens, and other places where people congregate and have a little leisure, and may desire to give or get photographs of themselves and their friends at little expense in money or time, and thus be greatly appreciated and taken advantage of for taking photographs or pictures of persons or simple objects.

The nature and novelty of the invention, and new or improved automatic mechanism, under one arrangement, consist all as follows:—In securing by their case a suitable set of photographic lenses with mechanical or pneumatic closing diaphragm or shutter on the inside of the front wall of the dark box through or opposite a hole at a proper height to let the rays of light in through the lenses from the person or object whose photographic picture is to be taken. Within the back part of the dark box a great number or set of the small (preferably rectangular) properly prepared sheet metal plates (or it might be cards or paper) on which the pictures are to be taken would be mounted as close together as possible by their lower edge in slit clip bars or equivalent on endless bands or chains traversed on two end rollers (preferably vertical), but it might be horizontally, or they may be so mounted on the edge of a rotating wheel, in any case so that each front plate left, as the others are removed and used, would be brought round and forward up against a stop guide, preferably in a vertical position over the top roller, nearly in line with the lenses, by a weighted cord passed over a cone pulley or fusse on the roller, which would remove it out radially from the other plates behind it at the top edge. Each plate is thus set under and ready for being caught by a pair of spring finger grippers jointed to project down from the long arm of a beam or reverse two-armed lever, so mounted in its normal position on its round longitudinal spindle, fitted in end bearings at one side of the box, as to be oscillated down on or by its said spindle, and be successively traversed along it over a set of the necessary chemical and water washing baths to be oscillated, and dip the plate once or twice into each bath at each traverse forward to complete the picture, mainly by this automatic acting lever, after the money is put in the slit of the box and the outer handles are moved. The said treating baths are preferably formed narrow, say an inch or so in width, to require the least convenient traverse of the plate and lever between the supply plates at the back of the box and inner end of lenses, where the baths are ranged preferably mostly in one porcelain vessel with only division walls between them, or portable and removable from between the walls, and of a depth and width to ensure that the liquids in them would remain clear and in good working order. The chemical and collodion baths might be portable and separate from the others for ease of removal and refilling, and have light spring flap lids for remaining close to prevent evaporation of the ether from the collodion except when the plate is being inserted and withdrawn, which opening and closing of the lid may be effected by a wedge rod action, or other

equivalent, moved by the lever which dips the plate into the bath. Each water bath would be supplied from a cistern in the top of the box stand, led by a small pipe and controlling tap to holes across the lower part, to ensure a clearing motion through the whole bath. The water would be kept at a nearly uniform level in the bath by an open or syphon overflow tube, which would convey the waste water down to a cistern fitted in the lower part of the stand box, and have the water supplied to and removed from these cisterns daily, or from time to time as found necessary. The short back arm of the said oscillating and traversing lever (which so catches, traverses, and dips the plates in the baths to have the pictures formed on them) traverses along a horizontal guide and stop bar in the highest or normal position of its long gripping arm. This traversing of the lever step by step forward on its horizontal spindle over the respective baths is, by our arrangement, effected by a light chain or light steel band, or other equivalent, having its one end secured to the front of the boss or short arm of the lever, and round guide pulleys carried on the sides or fixed cross rails of the framed stand box, to and wound one or more turns round a reverse weighted or spring take-back motive drum or barrel, and has the other end conveyed over reverse guide pulleys at the other side of the box, and attached to the back end of the boss or short arm of the lever. All so that as this motor and stop barrel are turned intermittently in one direction or forwards by the several spindles with their handles outside, as will be described, it draws the lever over the several baths to dip the plate as explained, and also winds up a weighted light chain or steel band on its periphery, which, when the lever has passed over the last water washing bath and delivered the finished plate with the portrait on it, the last and lowest spindle with its handle outside will release the stop catch from the barrel, which will by its weighted chain turn backwards and draw the plate lever by its endless chain or band back to its starting position again ready to grip and treat a new plate. The top end of each plate is punched with a hole, or it might be otherwise indented or roughened, so that the hinged gripping fingers will grasp the plate securely; and the grippers would have short arms above the fulcrums, which could be compressed to open them against the power of their spring to release the plate. The spindle of the plate gripping, oscillating, and traversing lever is made parallel or cylindrical, so that the eye of the lever may fit it and slide and oscillate freely on it in all its positions except the first, where a projection on the spindle, when turned by its handle outside, comes in contact with a projection on the boss of the lever and causes the grippers on the lever to descend and catch the plate and raise and remove it out of its holder on the back or return action of the spindle, effected by the power of a reacting weighted cord or spring. By one suitable arrangement of the mechanism for so first traversing the plate-gripping lever and then oscillating it to dip the plate, seven other horizontal reacting oscillating spindles are mounted in bearings inside, some distance below the first spindle, with similar acting handles outside, all preferably on the left hand front side of the close stand box, with arrows over them to show the direction in which to turn them, stops preventing them from being turned too far in either direction by the hand or by the reacting springs inside, a half of a circle being the maximum amount of turn required. The long arm of the lever of the plate-grippers or fingers has a hanging pulling-down rod or bar jointed to it at top, and free to move at the lower end in a suitable guide, having open pulling-down gals or snags at a suitable distance above and out from each of the seven actuating spindles, so that wiper arms on these spindles in the plane or line of the several baths will come down and take into the respective gals and pull the lever down as soon as it has been shifted along its spindle by its endless chain and stop reacting barrel opposite each bath and wiper of the spindle, so moving it in both directions. Each of the seven spindles below the first has an abrupt cam or anti-friction roller on it, working over a suitable raised intermediate part on a long transverse lever mounted below it, fulcrumed at its inner end, and having jointed to its outer end a pendant pushing rod or bar reciprocating in a guide frame below, so that its lower end, or a projection on it, acts preferably direct on a pushing and retaining projection on the periphery of the weight or spring reacting motor barrel. Each cam lever has a hanging retaining stop bar fulcrumed over it to a part of the frame, and which comes into action over the lever by its own weight each time the lever is depressed to turn the barrel and hold the lever and barrel there until the next spindle and handle outside is turned to actuate the barrel by the first motion of the next spindle and its upper lever as the strain is taken off the former lever and its holding bar, which is then withdrawn out of the way for the backward motion of the barrel. These levers with their acting cams are all ranged preferably as close as convenient towards the back of the box over the barrel, so that the pushing rods can all work in one guide, with their ends or projections reciprocating and acting tangentially to their projections on the periphery of the barrel which they intermittently turn gradually further round by having the projections mounted spirally stepwise round a part of its periphery. In the front of the case a recess is formed to the right, or one side of each spindle, with a light raising and lowering shutter or semaphore inside opposite each recess, having simple instructions on it how to actuate each handle, and which is removed as each handle is actuated, and then by its reaction brings the semaphore of instructions of the next handle below it into view. This is effected by light oscillating levers with hook rods actuated by each spindle and handle, which raise the said instruction lever of the handle below it, and by its back action release or lower its own instruction handle out of view by disengaging the lever from its raising rods, each in succession, until they come to the last handle, which by its back action releases the top semaphore to give the instructions again for the first lever, for the taking and delivering of another photograph. The box in front would have a low chest or table part projecting forward to the distance the person required to stand in front of the lenses, and a screw hassock or stool would be fitted there in front near the floor, preferably with a screw and hand wheel over the table part for conveniently raising this stool to any height to suit the height of the individual whose photograph was to be taken, and raise him in line with the lenses for taking a bust likeness with his breast up against a steady rail or other equivalent for setting him up in proper distance focus from the lenses.

A further improvement consists in having a folding-up part of the table or

other equivalent, with a mirror fitted on or over it, in proper distance focus, and at such an angle that when the person whose photograph is to be taken stood in a position close to the dark box convenient for working the handles, he would turn his face towards the mirror, which might have a nice fancy oval frame, so as to take his likeness from his reflection in the mirror instead of from himself. To ensure that the likeness of the person would be taken in the centre of the oval or other fancy framed mirror, a small oval regulating mirror is set near the large one, opposite or at right angles to the position in which he stood, but at such an angle to the large mirror that when he places himself so that his image is in the centre of the small mirror, it would be in the centre of the large mirror in relation to the lenses, and in true focus to the lenses and plate inside on which the image is to be taken, owing to the angle and position of the large mirror being set the same to the person as its angle and position of reflection is set to the lenses. A mechanical self-closing diaphragm or shutter would be fitted in the lenses inside, either in connexion with a pneumatic tube, or with a pulling and turning handle mechanism, which would open the lens for any number of seconds, according to the instructions given on the semaphore of the third handle, by the person outside placing his hand on and depressing a knob in connexion with the pneumatic tube or on the said lever for the said time, the diaphragm closing as soon as the person raised his hand.

The action of the internal mechanism of this automatic photographing machine, and the procedure and simple operation of the said eight handles outside by the persons desiring to have their photograph taken and delivered by the machine, consist all as follows:—Following the simple instructions on the outside and on the semaphore label of the upper handle, the person first puts the coins into the opening for receiving them, the weight of which tilts the receiving box lever, so as to unlock the spindle of the top handle and deposit the coins into a till; the person then turns the top handle slowly round in the direction of the arrow over it, which brings down the before-mentioned gripping lever to catch the plate on which the photograph is to be taken, the reaction of a spring or a weighted band takes back the handle and spindle to their normal position with the gripping lever in its highest position, clear of the top of the baths and in line with the lenses. This motion of the top handle releases a simple locking catch of the second spindle and brings the instruction semaphore label into view for the action of its handle, to turn it slowly round once or twice and hold it there for the number of seconds stated, which action would cause the mechanism inside to draw the plate and lever over the collodion bath and dip the plate into this first bath to coat it. The automatic motion and mechanism of this second spindle also raises the lever and plate to their highest position and frees the locking catch of the third spindle, so that its handle can then be turned in like manner to bring the plate over the second or nitrate of silver bath and dip the plate in it once or twice and give it the number of seconds required to sensitise the collodion surface, the internal mechanism would then bring the sensitised plate to its highest position in the true line and proper focus distance to the lenses to take the portrait when the person, following the instructions brought into view for this stage and handle, went and stood steadily on the stool in line with the lenses and raised their closing diaphragm by the pressure of a finger for the number of seconds stated on the label of the handle, all as hereinbefore described. The picture would then be taken by the light on the plate, so that the turning of the next or fourth handle (now unlocked by the motion of the former handle) to the instructions brought into view would, by the internal mechanism, bring the plate over and dip it into the third or developing bath of the protosulphate of iron (or other suitable mixed developer) for the number of seconds stated. In like manner, the turning of the fifth handle to the instructions brought into view would bring the plate over and dip it into the fourth or water washing bath for the number of seconds stated. Then the sixth handle, like the others, would be turned once or twice for the number of seconds according to instructions, which would cause the internal mechanism to bring the plate over and dip it into the fifth or clearing bath of hyposulphite of soda, or other suitable clearing agent. After this the seventh handle (previously unlocked like the others by the motion of the handle above it) would be turned for the number of times and seconds stated on its label or semaphore, which would cause the internal motive mechanism to bring the plate over the sixth or final water bath, and wash or dip it therein conform to the instructions given, controlled by the person actuating the handles or getting the photograph. To give a thorough washing of the plate and picture in the two water baths, a corrugated or serrated hollow segment would be mounted in the plane and arc of the plate grippers jointed on the end of their oscillating dipping lever, all so that a light spring or arm projecting from the grippers would act on the roughened surface of the segments and vibrate or shake the grippers and the plate edgewise while being oscillated up and down in the water by the plate-dipping lever. A last motion of the eighth handle would, after the plate was so washed in the last water bath, bring its lever forward beyond the plane of this bath over an angled spout, and the upper ends of the grippers above their joint in contact with a V-shaped or other equivalent relieving arm, which would open the grippers and let the plate slip down on its back with the picture upwards into an inclined channel, which would deliver it on to an open receiving tray shelf outside the front of the machine, convenient to be picked up by the person so putting in the money and controlling the action of the machine to the instructions given, and which being carefully observed would by this well-adjusted and arranged combination of self-acting or motive mechanism produce a very fairly good photographic picture or likeness. The last motion of the eighth or lowest handle outside would unlock the holding catch of its own instruction semaphore lever to let it fall out of view and that of the first top handle to let it fall into view, as well as release the motive weighted band or spring acting barrel, which would then take back the plate gripping lever on the upper spindle to its first normal position ready for being brought down over another plate as soon as the prescribed copper coins were again put into the receiving channel.

All the spindles with the handles outside, for sequentially and intermittently enabling the mechanism inside to automatically perform the several operations described, are all fitted with simple locking and disengaging mechanism to prevent the handles being tampered with outside, except when the money is

placed in the slit and actuates the disengaging lever of the first spindle and handle outside. One simple construction or arrangement of this locking and disengaging mechanism consists in having a short lateral projecting pin or lever secured in each spindle inside the box, and having mounted over this a vertical oscillating lever, the end of which locks the said pin and its spindle by its own gravitation, falling vertically over the said lateral pin when allowed to do so out of its retaining spring catch. Each spindle is provided with another short projecting pin, which disengages the holding out catch of its own locking lever, either in its forward or backward reacting motion, which holds it out of action when disengaged by a cord or other equivalent attached to and actuated by the spindle above it. The spindles and their handles would thus act in succession to disengage the locking lever of the spindle below it, and lock itself after each action.

The projecting lever on the first spindle, however, is locked by the heavy end of the money lever, which is relieved when the full weight of the coin is put in, and comes up against or over a horizontal hanging stop or catch, so as to allow the first handle and spindle to be turned; but the back action would by its second projecting pin take this stop out of action and allow the money to be discharged into the till, when the heavy end of the lever would again come back by its own gravitation and lock the spindle.

This photographic machine may also be used and made to act in rooms or places at night, or where there is insufficient sunlight, by having an electric or other strong artificial light fitted for use on the top of the box or where the light would act on the person or object being photographed, or on the mirror where that is used.

Other arrangements of reacting spring or weighted band motive mechanism may be employed as an equivalent for the spring or weighted band barrel described for bringing back the plate gripping lever on its spindle to its starting normal position, after having delivered each photographed plate; such as a spring, or a long lever actuated by a spring or weighted band acting over a guide pulley at one end of the machine, the plate traversing lever being brought forward by the turning, pulling, or pushing action of the eight handles, step by step, each one in succession relieving the previous turning, pulling, or pushing lever or rod of the motive spring lever brought into action by the previous spindle and handle above it.

Instead of traversing the lever, which carries the clip and raises and lowers the plate or card on which the photograph is to be taken, by sliding its boss on a fixed spindle, as described, over the baths, this spindle might be made in the form of a screw, and work in a corresponding hollow screw in the boss of the lever, so as to traverse the lever when the screw spindle was turned. The screw spindle is turned by a spur wheel on its one end gearing into an intermediate wheel, working a spur wheel on the corresponding end of another spindle mounted in bearings parallel to the screw spindle, with short lever tappets and curved cams on it, both spindles being turned by a spring or weighted cord barrel or other equivalent motor. The times of the motion or revolution of these two spindles would be regulated by a separate time motor with a regulating fan or other equivalent set in action by the insertion of the coins as hereinbefore described. In this arrangement the various outside handles and their spindles for regulating the action and intermittent traverse of the lever would be dispensed with, as also the stop barrel, and the screw spindle being set in motion would gradually traverse the lever over the baths; and the cams and tappets would be so arranged on the spindle geared parallel to the screw spindle as to act on the back short arm of the lever and raise the front long arm and the plate on it out of the baths while being traversed along the screw, and regulate the pauses the lever had to remain down with the plate in the bath, and be held up to give the exposure and be traversed by its screw spindle. The screwed boss end of this lever might be in the form of a half circle, and weighted so as to retain it in its traversing screw, but have it so mounted with a loose longitudinal bar in the segmental boss above the screw that when the lever was traversed to the far end of its screw spindle this bar would be released by a disengaging cam or pawl arrangement, and raised so that the lever could be traversed on this bar as an inclined plane, on rollers or with a cord and light weight to the starting end of its screw, where it would also cause the sliding bar to fall, and the screw boss of the lever to fall into its traversing screw spindle ready for receiving a new plate, all otherwise substantially as described in reference to the former arrangement of traversing the bar. Instead of having the baths ranged stationary in a straight line under the traversing lever carrying the photographic plate, the baths might be ranged in segmental divisions round a circular tray under this lever, which in this arrangement would be moved so as to rotate on a spindle or centre over the baths, by having a screw wheel on the boss on which it is jointed and oscillated, actuated by a screw spindle working into the wheel, and the back end of the lever be actuated so as to raise and lower the lever with the plate on it by a fixed or rotated ring cam ranged concentrically round its axis, the projections and hollows in the cam regulating the position and pauses of the lever in its lowest and highest positions, in bringing the plate over the baths and in front of the lenses for having the photograph taken otherwise substantially as described in reference to the former modification, the plates being held by the clips and lever either radially or parallel to the lever or tangential to the circular troughs at right angles to the levers.

In this modification or arrangement in which the chemical and washing troughs are set stationary within a circle, the lever arm carrying the gripper and plate to be operated on might oscillate on a fulcrum on a vertical shaft carrying it round with it over the troughs, and actuating the slide of the grippers within slotted guides projecting down from an arm and bracket carried over the lever on the rotating shaft, both the lever and bracket being counterbalanced by weights on the opposite sides of the shaft, which might revolve in footstep and top journal bearings in a frame erected in the centre of the dark box or camera. One mode and means of rotating the shaft would be by a large bevel wheel secured near its lower end, say, with 144 teeth by a bevel pinion with 12 teeth. The shaft of the pinion would be actuated by increasing speed spur gearing from the weight and cord motive spring barrel, each revolution of the pinion giving one-twelfth of the circle of the shaft, and twelve revolutions the complete circle of the central shaft, carrying the arm and clip with the plate to be photographed respectively, each

division of the circle of troughs and round the whole circuit to complete a picture and deliver a photographic plate. The times of the revolution and pauses of the said pinion shaft would be regulated, as before stated, by a stop pin in the shaft and engaging and disengaging lever controlled by the light motive time regulating weighted cord or spring barrel mechanism, set in motion by the coins placed in the slot and box lever mechanism for that purpose. Sectional divisions would be cut between the chemical and water troughs at the parts round the circle, where the plates had to be photographed and dried after fixing and washing, and after being varnished, and where the plate had to be delivered, and another new plate picked up during the pause of the lever carrying the picture over these divisions, preferably in this case having the pauses while the lever was in its lowest position, with the photographic plate within the troughs, or in front of the lenses to be photographed, or over the light to be dried. The oscillating motion is given to the lever carrying the photographic plate (to raise the plate out of the baths and leave it in the new bath or position as they are carried round with the shaft for taking the photograph and drying the plate) by a connecting rod carried down to a small crank shaft mounted in bearings under and parallel to the lever, having a bevel pinion with twelve teeth on it working into a large bevel fixed wheel or rim with 144 teeth in it, not rotated by the shaft, but concentric with it, and corresponding to the bevel wheel fixed on the shaft, so that each movement of the shaft during one-twelfth of its revolution makes the crank shaft rotate one revolution, and reciprocates the lever up and down as described during that revolution, leaving the lever and plate always in the same lowest position ready for rising again, which is preferably at the forty-five degrees of the crank, having raised the lever and plate a little from their lowest position for making the pauses within the boxes, or for drying and photographing the plate, and enabling the plate to clear the top of the boxes while rotating with the lever and shaft. The pauses are regulated as before stated by the secondary time motor stopping the bevel pinion shaft which actuates the vertical shaft, and which, as described, moves the secondary lever reciprocating crank shaft. The shaking motion is given to the plate within the baths in this arrangement by a small radial spindle mounted over each bath, actuated by pinions from a bevel wheel rotating loose on the central spindle, and operated by the motor which regulates the time movement, and by a knurled wheel, as before stated, acting on a lateral spring lever connected to the spring clips carrying the plate. In this arrangement the plates may be carried on an endless band, or large rim wheel, by their lower angled ends being brought up vertically under the clip in the position where it seizes it when its lever is going to make its first motion after the cams are inserted into the apparatus.

Under another modification, or modified arrangement of the parts of this apparatus, instead of the lever which grips the plates on which the photographs are taken being traversed over a stationary set of baths, it might simply reciprocate in one position after gripping the plate, and have the baths arranged radially in equal divisions round a circular rotating tray or radially divided frame, rotating horizontally on a hollow rotating vertical spindle; which spindle might be made to supply and circulate the water to and from the several water baths, which, as well as the other chemical baths, would preferably be made portable and segmental to fit the divisions in the rotating frame. This rotating frame might be divided into twelve or other suitable number of equally divided segmental spaces, with a ratchet wheel on its spindle having a corresponding number of teeth to the segmental divisions of the rotating frame, set and actuated on the lower part of the spindle, which would revolve on a footstep bearing below, and a steading bush bearing above secured to the frame of the machine. One sectional segment of the rotating frame of troughs would be cut away right through where the wheel frame stopped at each rotation, under the lever which picks up each photographic plate brought round radially for that purpose under the clips of the lever after each revolution of the radial trough frame, which would be rotated by a small crank shaft and horizontal ratchet spring pawl connecting rod made to pull or push it round one tooth of ratchet wheel and division of the frame at one time for each revolution of the crank shaft. The crank is rotated by a spring barrel, or a cord and weight barrel within the case, or by an electric or other motor, and ranged horizontally in line with the ratchet wheel, which cord and weight might act through speed-reducing and power-increasing pulleys, so that the weight would not require to traverse through a very deep recess or case to give two or three hundred revolutions of the crank shaft, twelve revolutions of which would be required to make one revolution of the trough frame and complete and deliver each photographic picture. Another crank would be formed on this crank shaft, with a vertical connecting rod, having its upper end connected to a reciprocating segmental lever, the outer periphery of which might either be toothed as a toothed segment to work on a toothed rack, or other equivalent with steel bands or chains, on the reciprocating plate or frame of the gripping clip which caught the photographic plate and actuated it, so as to pick up the plate through the open section in the frame and bring it down into each bath as they were brought in succession under it by the ratchet pawl and other crank of the shaft. The different times of rotation of this shaft and pause during which it would stand still for each of the several operations—of coating the plate, sensitising it, exposing it to the light to take the photograph, developing the picture, washing it, fixing it, washing it again, drying it, varnishing it, and drying and delivering the picture, and picking up another plate to be similarly operated on, constituting the twelve revolutions of the crank shaft and operations of the cycle for producing and delivering a picture—are regulated by another spring or cord and weight barrel time mechanism and arrangement of gearing with regulating fan or other equivalent; and of a light character, requiring only the power to actuate the engaging and disengaging stopping lever of the crank shaft which has the greater amount of work to do, the weight of the coin or coins inserted into the apparatus setting on this time mechanism for each revolution of its regulating, engaging, and disengaging wheel. The division teeth of this wheel correspond in number and distance between them to the times or pauses between the twelve revolutions of the crank shaft, each of a different length corresponding to the time of the pause between each revolution. The thin photographic plate would be mounted, as hereinbefore described, on lateral blocks, or slips of wood

mounted on an endless band the depth of the plates, traversed in this arrangement horizontally on loose vertical pulleys in front of the spindle of the radial trough frame, and round guide pulleys behind it, all with rim flanges to keep the band and its slit holders and plates in a horizontal vertical position, so that each plate would be brought into radial position under the vertically reciprocating gripping clips to receive it up through the blank section in the revolving segmental frame as this frame made the last motion of its circuit by a pin or other equivalent. Or the plates might be mounted on the periphery of a drum or pulley instead of an endless band. Each plate would be made of an angled or pointed shape on its other side, so as to more easily drain off all the water or liquids at the said angled central point; and under this radial position of the plate below the absent section of the frame a reciprocating plate, or frame gripper, would be mounted in guides analogous to the upper gripper, which would take on to the lower end of the plate, and by another segmental lever be raised so as to remove the plate from its band and place it into the grippers of the reciprocating arm above the baths at each twelfth revolution of the crank shaft. The crank shaft might actuate another short shaft through a pinion and wheel with teeth in the ratio of one to twelve, and a connecting-rod from this crank shaft be made to actuate the lower segmental lever of the under reciprocating gripping plate or frame which placed the plate into the upper grippers each time the segmental wheel made one revolution, the plate being steamed in guides in the open section of the rotating frame. During the pause of the plate in its lowest position within the baths, a shaking or vibrating motion would be given to it by its gripper on its reciprocating arm by a light projecting or spring lever on it taking over a knurled or ratchet wheel on a light spindle turned by the time-regulating mechanism before mentioned, through light spur gearing. The plate, when lifted up by its gripper to the highest position, after removal from the sensitising silver bath, would make a pause opposite the lens and hole in the front of the case for taking the photograph. This pause or time would be determined by the person acting on the instructions written on the outside of the case to give the desired time for exposure according to the strength of the light. And the time motive mechanism, or the trough rotating frame during its last motion, would release a pulling handle, or a moving lever brought outside, for the person getting his photograph taken, to regulate the time of the exposure by opening and closing the diaphragm or shutter of the camera, according to instructions, while he was in this position. The two sectional segments in the rotating trough wheel would be open up through at the parts where the photographic plate was brought down to be dried, after being fixed and washed, and also after being varnished, and the last motion of the trough wheel in coming to these positions would swivel or raise a gas lever tube and burner at these times and positions by a cam and tilting weighted lever mechanism, and open the light when the gas tube was brought under the photographic plate to dry it, and nearly close the light when removed from under the plate. The second last sectional motion in the circuit of the trough frame would be made to release the grippers and allow the photographic plate, with the picture completed, varnished, and dried, to drop into an inclined shoot under this open section of the rotating frame out through a slit in the front of the enclosing box into a tray or into a drawer, which can be drawn out by the person. By one arrangement the water is supplied to the segmental washing boxes of the rotating radial frame down through the central hollow spindle direct or through an indiarubber pipe with stop cock from a cistern in the upper part of the enclosing box of the apparatus, through the hollow eye or spindle of the wheel rotating on the said hollow tube as a fixed spindle and through inlet openings or ports in both spindles, the overflow water passing down through corresponding exit ports and holes separated off in a lower part of the spindle by a division in it, and from the lower part of the centre tube down into a receiving trough in the bottom of the enclosing case of the apparatus. Each trough is filled by its inlet ports while traversing towards the open division under the plate where it has to be washed, and is emptied while traversing the part of the circle from where and after the plate has been washed, thus giving fresh water for the washing of each plate. Or otherwise the fresh water might be circulated through these washing baths only while they were in the position under and with the plate moving in them while being washed. And as soon as the trough frame or wheel is turned it closes these ports in the spindle and prevents the water circulating through the washing boxes except when required. The rotating spindle is fitted with close watertight ground or packing rings above and below and between the said inlet and outlet ports to prevent escape of water at these working surfaces to waste, except direct and while being filled and emptied through their said inlet and outlet ports.

The novelty and improvements of this invention are the method or mode and means of taking and delivering photographic portraits or pictures within a dark box or large camera of persons or objects set up outside and on suitable plates or cards supplied and treated within the dark box, by the arrangement of motive power and time weight or spring regulating mechanism (analogous to a simple clock movement) performing the numerous operations required, all automatically and sequentially or in a cycle of properly regulated intermittent time movements merely started by the insertion of the coins, and stopping itself after the delivery of each picture, merely requiring one movement of a handle or handles on the part of the person deciding to have the picture to adjust the exposure by instructions approximately to the strength of the light. Many of the details of the mechanism are susceptible of considerable modification, but the essential organs and their functions of the improvements or invention are—the making of the one motor or mechanism to do the main power work of the operations, namely, bringing the cards in succession as required to the vertical reciprocating gripping lever and reciprocating it, so as to take hold of the card and traverse it sequentially over equally divided-off chemical and water troughs and spaces between them, for drying and delivering and for receiving a new plate, and either ranged stationary in a straight horizontal line or in a circumferential horizontal series, or it might be by rotating or reciprocating the troughs or spaces in an equivalent manner under the reciprocating lever; and further, in causing the lever to reciprocate up and down intermittently while making each movement, the up and down movements and pauses between these reciprocations of the lever being controlled by the light time motive mechanism intermittently

setting on and stopping the segmental motive traversing mechanism of the lever, or of the troughs when they are rotated or oscillated, the time mechanism automatically stopping both motors after each cycle of operations, until other coins are inserted, which starts the time-controlling mechanism again for a new cycle and taking and delivering a photograph.

IMPROVEMENTS IN PHOTOGRAPHIC CAMERAS.

No. 7432. SAMUEL DUNSEITH MCKELLEN, Spring-gardens, Manchester.—
May 19, 1888.

My invention is intended to facilitate the use of an oblique mirror in connexion with photographic cameras, and is especially intended to be used in so-called "detective" cameras.

For this purpose I place a ground glass focussing screen on the top of the camera, instead of as usual upon the back. The position of this ground glass is usually at right angles to the sensitive plate in the camera for exposures. Midway between the positions of the ground glass and the sensitive plate I place a mirror in such a way that the plane of its reflecting surface exactly bisects the angle formed by the ground glass and the sensitive plate. This method of focussing by means of an oblique mirror was adapted many years ago by a Mr. Sutton.

The mirror, when in position for focussing, is made to fit close down upon a frame, which prevents any light passing to the sensitive plate, either from the lens or the ground glass, but as an additional security against any light passing through the focussing screen I make the focussing glass of a non-actinic colour. Various colours may be used, but I find light yellow all that is required.

The lens is attached to a front which moves backwards and forwards by the action of a rack and pinion in the usual way.

The whole arrangement is enclosed in a box, by preference of an oblong form, having four sides and two ends. The front end is pierced with an aperture of the proper size to allow the light to pass to the lens. The top of the box is cut out so that the ground glass is visible through the opening, and a cover is hinged to one side of this opening, which folds down and covers the ground glass when not in use. The front is made with two thicknesses of wood, with a space between to allow a slide to move up and down freely. This slide is connected with the before-named cover, so that when the cover is opened up to allow focussing to be done, the slide moves away so as to allow the light to pass to the lens, and when the cover is closed down, the slide covers the aperture in the front. But, as in some cases it may be desirable for the cover to be closed when the lens is open, I have arranged a connexion between it and the slide in such a way that the attachment between one and the other may be readjusted so as to allow the cover to be closed whilst the lens aperture remains open. The front of the box is hinged, preferably at the top, so as to enable it to be opened in order that the lens stops may be changed. To ensure that no light shall pass into the camera, except what passes through the lens, I fix an opaque flexible diaphragm inside the box, and between the lens travelling front and the box front. This diaphragm is attached by suitable means to the inside of the box sides, and the centre of the flexible diaphragm is attached to the travelling front, near to the lens flange, so that the travelling front may move backwards or forwards for focussing.

The exposure may be either slow or rapid. For a slow exposure the slide working in the box front may be used, and any length of exposure may be given by that means, the mirror first having been lifted on its hinges out of the way of the sensitive plate.

To raise the mirror I use a spiral spring working inside a roller at the top of the box, and a winding roller at the bottom, with a curtain between the two rollers, in the form used by Mr. B. J. Edwards in his well-known shutter. The middle of this curtain I attach to the front rail of the mirror frame. The curtain is first wound on to the bottom roller by the hand. By so doing, the mirror is drawn into its oblique position for focussing, and is prevented from returning by a click acting upon a ratchet attached to the bottom roller. The releasing is done by removing the click from the ratchet, either by hand or by pneumatic action, when the upper roller is caused to revolve by the spiral spring within it. This rolls the curtain upwards, and carries the mirror with it as far as it will go towards the top of the box.

An aperture is cut in the curtain in such a position that, when the mirror is in its position for focussing, the aperture will be opposite the back of the lens, so that the rays of light may pass from the lens to the mirror, and thus to the focussing screen. Another aperture is cut in the curtain, immediately beneath the mirror, so that as the mirror rises to the top, the aperture is carried past the lens, and, in passing, the rays from the lens pass through it direct to the sensitive plate. When the mirror has risen to its highest the aperture is past the lens, and the opaque portion of the curtain presents itself and so blocks the rays. The speed of the exposure is regulated by the tension put upon the spiral spring, so that exposures of various rapidities may be given.

Other methods may be employed to give the exposure, as, for instance, instead of the opaque curtain tapes attached to the roller may be used, and an instantaneous shutter of any of the usual forms may be used with the lens, and released by the action of the rising mirror, one of the special objects of this invention being the utilisation of the movement of the mirror out of its oblique position to effect the opening and closing of the lens.

The mirror may also be arranged to rise to the horizontal position without being in any way connected with the shutter, and the shutter may be made to open and close by pneumatic action, or by the action of the hand, without being acted upon by the mirror frame.

The claims are:—1. In a photographic reflecting camera, the use of non-actinic coloured glass for a focussing screen. 2. In a photographic reflecting camera, the method of lowering and raising the reflecting mirror by attaching it to tapes, bands, or cords, or to a curtain, such bands, cords, tapes, or curtains working between rollers, substantially as described. 3. In a photographic reflecting camera, using the movement of the mirror to actuate a shutter of any convenient form, substantially as described. 4. In a photographic reflecting camera, the use of the revolving rollers to communicate motion to a shutter by

suitable connexions. 5. In a photographic reflector camera the use of the tapes, bands, cords, or curtain to actuate a shutter of any convenient form. 6. In a photographic reflecting camera the use of a curtain working between rollers to admit and exclude light from the lens, substantially as described. 7. In a photographic reflecting camera the use of a flexible diaphragm to exclude all light except what passes through the lens, substantially as described. 8. In a photographic reflecting camera the use of a hinged front to give access to the lens. 9. In a photographic reflecting camera connecting or disconnecting the top cover with the front cover, so that they may open and close together or separately as required. 10. The arrangement for stopping the movement of the mirror at the proper position for giving a prolonged exposure, substantially as described.

NEW OR IMPROVED PROCESS OR PROCESSES FOR THE PRODUCTION OF COLOURED PHOTOGRAPHS UPON GLASS AND LIKE SUBSTANCES.

No. 8518. AUGUSTE EMMANUEL LETALE, Mary-street, Balsall Heath, in the county of Worcester, and FREDERICK BILLING, Livery-street, Birmingham, in the county of Warwick.—June 11, 1888.

It is well known that alkaline chromic salts, such as bichromate of potash, prevent gelatine from swelling when treated with cold water, or dissolved, or made soluble in warm water, when light has acted upon the said gelatine or a film thereof.

Several photographic processes are based on the aforesaid properties of swelling and dissolving in water, viz., the Woodburytype, colotype, and carbon printing processes make use of or employ a photographic negative in order to render the gelatine insoluble in the parts where the said negative had allowed light to pass through.

In the Woodburytype process, the washing away of part of gelatine not rendered insoluble by light is also done in carbon printing, and in the colotype process in not washing away in hot water, the gelatine not insolubilised by light, but in swelling in cold water, for repulsing the greasy ink with which the gelatine is rolled over to produce a picture as is done in lithography.

Our invention consists in producing coloured photographs, upon glass, opal, china, and other like substances.

According to one part of our invention coloured photographs are produced by covering the aforesaid substances, or a part of the surfaces thereof, with a film of gelatine sensitised for light with a salt of chrome, and exposing the said sensitised and prepared film under a transparent positive, instead of under a negative, as in the preceding processes, as hereinbefore referred to.

Thus, for example, a plate of white opal glass is taken, and one side thereof covered or coated with a gelatine film sensitised for light by a salt of chrome. This plate is now exposed under a transparent positive, and then placed in a bath of cold water, and the salts of chrome thus employed washed away. The plate is then dried, and subsequently immersed in a bath of dye, containing a large proportion of glycerine (about one-half).

The parts of the film or surface not hardened by the exposure to light absorb or take up the dye and produce a photographic picture in the colour of the dye used.

The surface of the plate thus treated is then immersed in a bath of alum and left to dry.

Thus, the process, or the combination of processes in the production of photographic pictures on the surfaces of the materials as aforesaid, and according to our invention, consists essentially in employing dyes in connexion with gelatine films, or rather those parts not hardened by light under a positive.

According to another form of our invention, we use dyes in connexion with gelatine films as before described, but sensitised with perchloride of iron and tartaric acid, and with the said prepared and sensitised surface placed under a negative instead of a positive.

The plates are dried in a warm room at about 120 degrees Fahrenheit.

The dye solution is made by putting the colouring matter (which must be soluble) either in pure water, or in water and methylated spirit, with or without glycerine, gum arabic, or other bodies of a like nature or constitution added.

Our said invention is eminently adapted for the reproduction in colour of drawings, works of art, portraits from life, landscapes and other scenery from nature, advertisements, tablets, coloured windows, and for all other purposes where ordinary photography has been applied.

The surface substances upon which the photographs are reproduced may be of any colour desired.

Having now particularly described and ascertained the nature of our said invention, and in what manner the same is to be performed, we declare that what we claim is:—1. The production of coloured photographic pictures by employing dyes or stains in connexion with gelatine films, or rather those parts hardened by light under a transparent positive, as set forth. 2. The production of coloured photographs upon glass, china, and other like substances, by employing dyes or stains in connexion with gelatine films sensitised for light by a salt of chrome, and exposed under a transparent positive, and which said process of production, or the combination of processes, is or are conducted or carried out in manner and by means substantially as set forth in the first part of our invention. 3. The production of coloured photographic pictures upon glass and other like substances by employing gelatine films sensitised for light with perchloride of iron and tartaric acid, and placed under a negative, substantially as described in the second part of our invention.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—Tuesday, May 14, at eight p.m., at the Gallery, 5A, Pall Mall East, Mr. T. R. Dallmeyer will read a paper on *The Form and Applications of Single Landscape Lenses*.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting May 15, 1889, will be on *The Relation of the Focal Length of the Lens to the Size of the Image*. Saturday outing at Finchley, Church End.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

MAY 2.—Mr. William England in the chair.

The HON. SECRETARY read the following question from the box:—"What is the average weight of three-fold portable stands, each leg when extended being five feet six inches long, and what proportion of that weight is in the head of the stand?" The Hon. Secretary added that it was a most extraordinary question, and that the inquirer had better put another.

No public answer was given to the inquiry.

Mr. ARTHUR S. NEWMAN exhibited a detective camera which he had long been making, assisted by criticisms from Mr. L. Medland, to whom the instrument, whilst in course of construction, had been sent about a hundred times. It would, he said, carry twelve plates; all the working parts were underneath; it was fitted with a Wray's 5x4 doublet lens; it had a double shutter, that is to say, the window in front of the camera was opened first and the true shutter released next, both by a single movement of the finger releasing the detents; and it had what is known as Samuel's system of changing the plates. When one box of a dozen plates had been used another box could be put in its place. With twelve quarter-plates it weighed eight and a half pounds.

Mr. P. P. CEMBRANO presented a German circular he had just received about the introduction into the market of the camera of Anschütz, of Liessau, with a roller-blind shutter having a narrow slit, and said to be capable of giving exposures as short as the one-one-thousandth part of a second. The plates used measured 9x12 centimetres—a little larger than the English quarter-plate.

Mr. WILLIAM COLES exhibited two photographs of the same person and asked if any difference could be seen in the freckles of the sitter represented in each.

The CHAIRMAN remarked that one was a little better than the other, but they ought to have been printed to the same depth to allow a fair comparison to be drawn.

Mr. COLES added that one was taken upon an orthochromatic plate, and he could not see that it was any better than the other.

Mr. J. R. H. WELLINGTON exhibited views of the boat-race over which the exposures had been made with the roller-blind shutter, and he remarked that the pictures presented no visible distortion.

A question in the box asked whether shellac could be obtained which would form a perfectly colourless solution; if not, what was the best method of eliminating the colour.

Mr. A. COWAN thought bleached shellac to be always rotten.

Mr. A. HADDON believed it was bleached by blowing chlorine through an alcoholic solution of ordinary shellac.

The CHAIRMAN said that it was best to use seed lac; the spirit must be allowed to take up what it would without the application of much heat, otherwise an inferior kind of resin seemed to be dissolved out of the sediment, and that made the varnish soft afterwards. The bottle should be kept in a warm place for a few days and then the moderately clear portion poured off and filtered. By shaking this varnish up with animal charcoal it could be reduced to nearly a sherry colour.

Mr. COX had tried a method recommended by M. Vidal, and it had not answered in his hands.

Mr. L. MEDLAND asked the best known method of testing the speed of shutters.

The CHAIRMAN remarked that Mr. C. Wollaston had exhibited very good and simple apparatus for the purpose.

Mr. MEDLAND wished that there were a place to go to to have shutters tested on payment.

Mr. W. H. HARRISON said that about a year ago Captain Abney had published that photographic lenses would, after a time, be tested at Kew Observatory; perhaps shutters might be tested there also.

WEST LONDON PHOTOGRAPHIC SOCIETY.

MAY 3.—The President in the chair. Joint paper on *Enlarging* by Dr. Harrison Low and Mr. John A. Hodges.

Dr. Low, after some introductory remarks, said that enlarging was undoubtedly a good subject for discussion; the methods were various, and opinions upon their relative merits equally so. The advisability of getting "a large picture" appealed to every one; all were agreed that a large picture was better than a small one, within due limitations. He thought if all could work 12x10 size at the same expense and with the same comfort there would be small demand for quarter-plate cameras, and even the strictest Pharisee of the quarter-plate sect, the lantern-slide enthusiast, was but an enlargement man in disguise. He was aware that the production of big pictures by enlarging was not everywhere received with favour, but to his mind the taking of large pictures direct was put out of court by the large and costly apparatus necessary. His observations would be confined to enlarging direct on bromide paper. Opinions upon this method varied considerably, from eulogies (chiefly commercial) commencing "Permanency at last," to condemnations like "Bro-

mide prints are not worth the paper they are printed on"—the opinion given lately by a gentleman well known as a writer to the photographic journals. A far more weighty depressant had lately emanated from the pen of a Vice-President of this Society, whose book on *Naturalistic Photography* had caused some stir. Dr. Emerson considered, speaking of enlarging, it was, "in our opinion, a needless and undesirable proceeding." This, coming from a high light in our art, was another shock, and, but for the presumption, he (Dr. Low) should have thought the high light a little dense in this particular. (Dr. Low then proceeded to read extracts from the chapter on *Enlarging*.) Dr. Emerson's strictures on enlarging were to him the more surprising because they appeared to give that very broad pictorial effect so much advocated by him, and in many instances good examples possessed all the "tonality" of platinotype. Though disagreeing with the author on this matter, the book was one that should be read by every photographer. He pressed the claims of direct enlargement on bromide paper as opposed to making lantern slides and showing them upon a screen. He had come across clever photographers, whose knowledge of theory and practice was as an encyclopædia to an elementary handbook, who had not half a dozen decent prints to show, but who revelled in negative or transparency making. It was not, however, to be forgotten that to these gentlemen working in a scientific way mere picture makers were indebted for tabulated results, therefore he trusted his remarks would be taken good-humouredly. As to methods, he would only speak of daylight, leaving artificial methods to Mr. Hodges. His own mode of working had the great recommendation of being cheap, contrary to the apparatus recently exhibited at the Crystal Palace, which was said to be "just the thing for amateurs," and was only 14*l.* or 15*l.* If a room could be set aside for the purpose so much the better, but, personally, he had to do a "Cox and Box" performance with a relative who occupied a small upper room facing south-west; therefore he had to arrange that when Cox was there Box's arrangement should not interfere with Cox. (Dr. Low then demonstrated his method of working.)

Mr. HODGES said although he only proposed to deal with the various methods of enlarging by means of artificial illumination, he wished them to understand that he considered the results obtained by daylight were much superior, and that after a careful comparison of results he had abandoned the use of artificial light in favour of daylight. Artificial illumination, however, had many points in its favour; it enabled photographers to work at night and in dark weather, and the duration of exposure could be ascertained with a greater degree of accuracy. Broadly speaking, an apparatus for enlarging by artificial light embodied the same principles which applied to the construction of an optical lantern, and if the negatives were very small an ordinary lantern might be used, or if they were of larger dimensions a lantern transparency might be made by reduction in the camera and a small negative printed therefrom by contact, which could then be enlarged to any required dimensions in the lantern. Mr. Hodges then demonstrated the method of working an enlarging lantern. Speaking of illuminants, any form of limelight might be used, or, failing that, a flame of oil or gas. It might be taken as an axiom that the smaller the source of light the better would the definition be. An ordinary circular-wick burner would be found to give results equally as good as the very expensive parallel-wick arrangement, although the exposure would be slightly protracted. In regard to lenses, probably the best results would be obtained with a lens of the ordinary rapid type, preferably of longer focus than would ordinarily be used to take the negative. Attention to this point would ensure the attainment of better marginal definition and greater flatness of field. (Mr. Hodges then demonstrated the function of the condenser.) A form of lantern which dispensed with a condenser was introduced some time back by M. Hutinet, although the principle appeared to be old. It consisted of a chamber enclosing rows of gas jets arranged in tiers, which strongly illuminated a sheet of ground glass against which the negative was placed. A modification of this system, recently suggested by Mr. Ferraro would probably be found to answer the purpose better. He thought one reason why bad results were often obtained when using artificial light lay in the fact that artificial illuminants of low intensity did not possess sufficient penetrative power to enable the full scale of gradulation of tone in the negative to be reproduced. For this reason, when developing negatives to be enlarged, extreme density should be avoided. A negative inclining to thinness would give the best results. In regard to developing bromide papers he had found some brands apt to give hard prints, but they produced more pleasing results by modifying the developer. He used one part of iron to ten of oxalate, diluted with an equal bulk of distilled water. He wished to call their attention particularly to Alpha paper on account of the great variety of tones obtainable with it. It was very slow, but allowed great latitude in exposure. The colour produced by development might be modified by toning with any ordinary toning bath, or the ferro-cyanide intensifier might be employed, which would result in the introduction of brown tones. Mr. Hodges then referred to the production of enlarged negatives and advocated Mr. V. Blanchard's process, which was described in an old YEAN-BROOK as being a simple one to work and capable of giving fine results. In conclusion, he strongly advocated the practice of taking small negatives and enlarging therefrom. Working a large size meant a heavy tax upon one's purse, and the possession of a more than average amount of physical endurance and energy. He would ask why should the photographer who, from motives of economy or lack of physical strength, was compelled to adopt a small-size plate be debarred from the pleasure of seeing his work reproduced upon a large scale?

Mr. FOXLEY said that he had had considerable experience with artificial light, including the electric light and magnesium, but he gave a decided preference to daylight. The mode of illumination with paraffin lamps and no condenser spoken of by Mr. Hodges would be improved by using two pieces of ground glass placed about one inch apart. He thought the focus of the lens used by Dr. Low, six inches, was too short; a longer focussed instrument would give more equal illumination. Speaking of processes, if the negatives were suitable, bromide paper would give excellent results; if, however, the negative was not a very good one, a better result might be obtained by making an enlarged negative through the medium of a transparency. In reference to Dr. Emerson's assertion, that commercial enlargers examined negatives with a magnifier for the purpose of ascertaining that they were sharp, he would only say that that was contrary to his experience; in fact, he had known many

instances where the enlarged image was intentionally made a little out of focus. Mr. Hodges had said that he used a very weak developer with a very small proportion of iron; that was the way in which M. Nadar worked in producing his very fine specimens shown by the Eastman Company. He thought Dr. Low's arrangements would be improved by the employment of a reflector placed outside the window.

Mr. Broughton said it was hardly to be expected that Dr. Emerson would advocate enlarging. He seemed to aim at getting only one small portion of the negative sharp and the rest as much out of focus as possible. Such negatives naturally would not produce good enlargements. He had found hydroquinone in conjunction with caustic soda cause frilling. The addition of a small proportion of chrome alum was an effectual remedy. He had used a great deal of alpha paper, but had not obtained very successful results.

Mr. H. Selby had been able to produce a good range of tones on bromide paper with hydroquinone by lengthening the exposure and diluting the developer. He had also produced some warm tones with the uranium intensifier on under-developed bromide prints.

Mr. Foxlee said if Mr. Broughton used washing soda instead of caustic soda he would not be troubled with frilling. He always used it himself, and successfully.

Mr. Whiting considered artificial light better than daylight for most people, as the exposure could be more easily determined, and with the rapid papers it was more under control. Mr. Foxlee had said that some people threw their enlargements out of focus. That was a practice much to be deprecated. He referred himself a sharp photograph.

Mr. Blackmore said his remarks on ferrous oxalate development referred to negative work. With regard to the proportions of iron to oxalate, he would go further than the previous speakers—one to thirty worked well in his hands. He did not agree with the practice of diluting the developer with water to such an extent as had been recommended, as it tended to produce hardness in the prints. He had also noticed that a large proportion of bromide produced on an over-exposed print an unpleasant greenish tone; he had therefore discontinued its use.

Dr. Low was surprised to hear Mr. Foxlee speak disparagingly of the electric light. Personally he thought nothing could be better.

Mr. Foxlee said that the Eastman Company had gone to great expense in fitting up the electric light, but had abandoned it, and they now used daylight.

Dr. Low and Mr. Hodges having replied, the proceedings terminated. The members will meet on the towing path, under Richmond Bridge, at three o'clock on Saturday, May 25th, for an outdoor excursion.

NORTH MIDDLESEX PHOTOGRAPHIC CLUB.

MAY 6.—A lantern evening.

Mr. Chatham Pexton provided the lantern and worked it himself.

Slides were exhibited by Messrs. Humphries, Hiscock, Pexton, Beadle, Lathbridge, Cox, Walker, and Treadway.

A short meeting was afterwards held at which the Council announced that they had decided that it would be advisable to remove the Club to a room known as Jubilee Hall, in the Hornsey-road, which they had taken from June 24, there being greater convenience, a dark room being attached to it, and being next to the Hornsey-road Station, Midland Railway. This change would necessitate a slight alteration in the printed syllabus of the Club, it being necessary to hold the meetings on the second and fourth Monday night of the month instead of each alternate week.

May 20, technical meeting, Iron Room, Stroud Green.

SHAFTESBURY PHOTOGRAPHIC SOCIAL.

MAY 3.—Mr. Tollett in the chair.

The business was a show of Easter work by the members. Among the very many different views there were some very pretty views of Chidehurst by Mr. Tollett, and some instantaneous views of Chingford by Mr. Bull; there were also a set of the Portsmouth manoeuvres by Mr. Baker.

On Friday evening (to-night) Mr. Tollett will read a paper on *The Alpha Bromide Process*.

On Saturday afternoon, May 18, the members will go to Chingford.

EAST DULWICH AND PECKHAM PHOTOGRAPHIC SOCIETY.

MAY 3.—Mr. Warnerke in the chair. Lecture by Chairman on *Flash-Light Photography*.

Mr. Warnerke pointed out the great help flash light could be to both the professional and amateur, for the professional on dull days and for the amateur after the daylight had gone, who could then use it for portraits and groups. Mr. Warnerke showed the two lamps he used, which were both compact and inexpensive, and thought they could be had commercially. During the course of the lecture he took three negatives of the members of the Society, one of which was on Fry's celluloid films. He also showed the method of using the films in an ordinary dark slide, which method was both simple and efficacious. Mr. Warnerke showed a more powerful lamp which he used for copying prints, &c., and which would obviate the grain, and also that even if the original were much creased, the effect in the copy would be that none of the creases showed.

Six members were elected, and the names of ten gentlemen were proposed as members.

Next meeting will be held at 76, Peckham-rye, Friday, May 17, at eight p.m.

DUKINFIELD PHOTOGRAPHIC SOCIETY.

APRIL 23.—Mr. John T. Lees (Vice-President) in the chair.

Messrs. J. A. Armitage, A. Turner, T. Moores, C. Bates, A. M. Fletcher, and Dr. Park were elected members.

The first annual report and statement of accounts was read and adopted.

The report stated that the Society consists of fifty members, and the statement showed a balance due to Treasurer of 15s. 6d.

At a subsequent meeting of the Council the following officers for the year were elected:—*President*: Mr. John T. Lees.—*Vice-Presidents*: Messrs. John Ashworth, J. H. Brooks, and T. Glazebrook.—*Committee*: Messrs. S. T. Ainsworth, W. Chadwick, G. H. Dean, J. W. Hadfield, W. Jenkinson, and James Leech.—*Auditors*: Messrs. T. Borsey and A. Sampson.—*Hon. Treasurer*: Mr. J. Winterbottom.—*Hon. Secretary*: Mr. W. H. Shirley, King-street, Dukinfield.

COVENTRY AND MIDLAND PHOTOGRAPHIC SOCIETY.

APRIL 25.—The first outdoor meeting of the season to Kenilworth, Ashow, and Stoneleigh. There was a poor attendance of members, but a great many plates were exposed with fairly satisfactory results.

MAY 1.—Usual monthly meeting.—Mr. President Andrews in the chair.

The next outdoor meeting was fixed for May 22 at Lichfield.

A pleasant evening was spent examining the negatives taken at the outdoor meeting, and prints from them. Specimens of Mr. Blanchard's new process were also handed round.

BRECHIN PHOTOGRAPHIC ASSOCIATION.

MAY 1.—Mr. R. A. Scott, M.A., in the chair.

The chief business of the evening was the reading of a paper on *Stereography* by Mr. D. Waterson. Many practical hints were given on the preparation of pictures for the stereoscope, and there is no doubt that it will be the means of starting some to this most interesting branch of photographic science.

The cyclist's detective camera, by Turnbull, of Edinburgh, was exhibited. It was fitted with the Waverley express shutter, opening and closing from the centre, with which there is absolutely no shake.

The Secretary handed round some negatives on celluloid films (Carbutt's patent), which were thought an improvement on glass in all but price.

PAISLEY PHOTOGRAPHIC SOCIETY.

MAY 2.—Annual General Meeting.—Mr. Robert Harris in the chair.

The SECRETARY in his report stated that the past season had been exceedingly successful; thirteen meetings of the Society had been held, and the various demonstrations and lantern exhibitions had been highly appreciated. There were at present forty-two members on the books.

The TREASURER stated the financial position of the Society was very satisfactory, a balance being in hand after paying all expenses.

The following officers for the ensuing season were then elected:—*Hon. President*: Mr. Hugh H. Smiley.—*President*: Mr. James Donald.—*Vice-President*: Mr. Robert Harris.—*Council*: Messrs. Archibald F. Craig, James Mure, George Robertson, jun., James Reid, and William Holmes.—*Treasurer*: Mr. Matthew Morrison.—*Secretary*: Mr. Thomas Rastall, Inchinnan-road, Paisley.

A vote of thanks to the retiring officers brought the meeting to a close.

CINCINNATI CAMERA CLUB.

APRIL 1.—Dr. Carson in the chair.

Officers for the ensuing year were nominated, and subsequently, at another meeting, on April 15, the following were elected:—*President*: Mr. George Bullock.—*Vice-President*: Mr. William Hubbell Fisher.—*Librarian*: Mr. Arch. I. Carson.—*Treasurer*: Mr. Aaron Prince.—*Recording Secretary*: Mr. Emory H. Barton.—*Corresponding Secretary*: Mr. H. C. Fithian, N.W. Corner Fifth and Walnut-streets, Cincinnati, Ohio.

Correspondence.

Correspondents should never write on both sides of the paper.

RE PSYCHIC PHOTOGRAPHY.

To the Editor.

SIR,—Those who know everything there is to be known on all subjects they have not studied usually veil their ignorance of these subjects in sarcastic or repulsive ridicule. Your reporter is no exception to this rule, as exemplified in your issue of April 5, on *Psychic Photography*.

Mr. Edwin C. Middleton is probably aware that there are such things as imitation bank notes; also that there are imitation spirit photographers. He may also know that the fact that there are imitation bank notes in existence proves that there are not sufficient of the genuine ones about to please some people. The same thing is true in reference to spirit photography.

His knowledge also may inform him that none but a cunning, covetous, selfish person, who for years has been *successfully* deceiving and tricking his neighbours in trifles, would ever think of imitating bank notes, and that none but those who had the above qualities latent could allow themselves to waste precious time in imitating spirit photography; because all imitations are lies in act, done with intent to deceive, even if only in fun, and none the less a *sin*.

But Mr. Middleton's knowledge does not seem to carry him so far as to make him cognizant of the fact that no honest man accuses his neighbour of imitating bank notes until he has the proofs safe in his own hands; and your intelligent and thinking readers are looking for the proofs of the imitation spirit photographs or fraud Mr. Middleton witnessed I was the victim of, and none more so than myself. He is greatly mistaken if he thinks that your readers and myself will be satisfied with his pointing out that my assistant has drifted from an uncongenial trade into an artist without adding the usual brass plate ("Artist"); or that he was so simply natural as to come into such an august presence as Mr. Middleton's in the easy *déshabille* of his studio garb; or that because I have five or six large furnished rooms which I never use, and a school-room which will seat two hundred and fifty to let, while I go into the country for long periods to give myself up entirely to these experiments; or that his mis-statement asserting that Mrs. E— gave me the address of the artist when I distinctly told him "it was dangerous to give private names and addresses in the presence of his friend" (the reporter of the *Birmingham Daily Gazette*); or that I informed him that I never got phenomena unless the artist alone was present, when my plates sent to you, Mr. Editor, contradict that statement; or that because I was ill and incapable of the least exertion—in fact, had been ordered a three or four months' rest at the sea-side when able to be removed, and, therefore, could make no definite appointment—in any way go to prove that the humble man of refined feelings is a rogue, or that I am a victim of fraud. The age is progressive, and requires *proofs*, not assertions. I have sent mine to the Editor of THE BRITISH JOURNAL OF PHOTOGRAPHY—further than this every one must search for himself in his own family.

The Spiritual Evidence Conference affords enlightenment to inquirers, at which, periodically, there are sittings for psychic photography. The members can bring their own plates, and watch the process all through (but in a spirit of friendly inquiry—not as detectives). If Mr. Middleton does not think it worth a fee of 10s. per annum to support such a Conference, his desire for psychic light is not very great, and no person becomes clever with another's knowledge; it must be sought before it can be found, and found before understood.

I accepted as your deputy Dr. Norris, President of the Birmingham Photographic Society, a well-known experimenter, one well able to detect fraud, and who can also appreciate even small successful results. I still trust that before long he will see his way to devote some time and thought to a few experiments here.—I am, yours, &c., S. A. POWERS.

92, Ashted-rose, Birmingham.

P.S.—If Mr. Middleton will undertake to pay Mr. Bleasdale for paper, toning, fixing, burnishing, mounting, cards, and postage, I will undertake to see that these prints are supplied *free* to all who may apply for them. I only print a few from each plate, and the Conference members and friends soon take these.

[As Miss Power considers herself aggrieved by Mr. Middleton's report, we have thought it only right that she should be allowed to respond.—ED.]

RAPID COLLODIO-BROMIDE PLATES.

To the Editor.

SIR,—The announcement made at the time of last year's Convention of a new discovery by Dr. Hill Norris with reference to rapid collodio-bromide dry plates interested me much, and I have been patiently waiting for the formula, and now that it is published (and patented too) I must confess to a feeling of disappointment—such a lot of baths and dipping and draining.

Turning to an old number of the JOURNAL, pages 357 and 366 of No. 1309 of June 5, 1885, you will see a rapid collodion process given by Mr. Ernest Graham (page 357) and by myself (page 366), which in the hands of any real amateur (not a "shamateur") who buys everything and get his plates developed and printed for him ought to be a very workable process.

We have still many of the old collodio-bromide men living who could say a good deal, if they would, of their experiences with collodion plates and modern development. It would be a good thing if they could be induced to speak out as they used to do, but not through the columns of the patent reports.

For detective camera work and small lantern or quarter-plates, the process advocated by Mr. Ernest Graham and myself would be just the right thing, as the grain is very fine on these plates, and details come out very sharply defined, and therefore suitable for subsequent enlargement. The absence of halation is another strong point, the under film of collodio-bromide is very inactinic, and prevents the light from travelling to the back of the glass and being reflected again on to the image.

Heat has, no doubt, an influence in making these plates so rapid.

When experimenting with these plates I used to first coat glass with emulsion (collodio-bromide) and wash under the hot water tap at about 120°, and this would raise the temperature of the glass; then coat with gelatino-bromide emulsion and drain off; let set and stand up for drying, which was not a long operation. I found the plates twenty times quicker than collodio-bromide plates.

I invite others who have experimented in this direction to give to the public the benefit of their experience.—I am, yours, &c.,

GODFREY V. J. POIRIX.

Greyhound-lodge, Greyhound-lane, Streatham, May 3, 1889.

VALUATION OF HYDROQUINONE.

To the Editor.

SIR,—I am much indebted to Dr. Smith for pointing out an erroneous sentence in the abstract of a paper I read at University College. The connected sentence should run: "This quantity corresponds to a consumption of ten atoms of oxygen by each molecule of the hydroquinone." It will thus be seen that my experiments fully confirm those of Dr. Smith, with which, however, I was not at the time acquainted.

I may add that a solution of hydroquinone in tap water, which on April 8 had required 11.3 c.c. of permanganate for every 50 c.c. of the solution, after having been allowed to stand in a narrow-necked flask without stopper, required on April 24 only 1.4 c.c. of the same permanganate, and had at the same time become very brown.—I am, yours, &c., H. FORSTER MORLEY.

University Hall, Gordon-square, W.C., May 8, 1889.

A NEW SOCIETY IN HACKNEY.

To the Editor.

SIR,—In the name of the Hon. Secretary, Mr. Fenton Jones, of No. 1, King Edward-road, I have great pleasure in announcing to you that he has been successful in forming a photographic association at Hackney, N.E., which bids fair to become an important one. At the first meeting nearly thirty members assembled, besides which the Secretary holds numerous promises.

The proceedings, presided over by Mr. E. J. Wall, were of an enthusiastic character. After the rules had been agreed upon the following officers were unanimously chosen:—Dr. Gerard Smith, President; Dr. Kibbler, Mr. J. Hubert, Vice-Presidents; Mr. F. Jolly, Treasurer; Mr. W. Fenton Jones, Hon. Secretary.

It was decided that the Committee should be elected at the next meeting. The meetings are intended to be held fortnightly in the winter and monthly during the summer.

The entrance fee was fixed at 5s., with an annual subscription of 5s.—I am, yours, &c., J. HUBERT.

238, Mare-street, Hackney.

FLASH LAMPS.

To the Editor.

SIR,—In my letter on page 275 I only commented on the matter found in the notice on page 260. Mr. England should have known better than to have introduced fresh subjects for discussion, as he has done, in his mean attempt to disparage my apparatus, by saying that he "never failed but on one occasion," &c. (Certainly he dare not say that my lamps failed; every one present knows that they acted perfectly.) The public do not know the particulars of the case he refers to, therefore I consider it excessively mean to have made such an *ex parte* statement. Nevertheless, without the knowledge of the full case, the public has the opportunity of seeing his position with regard to flash lamps, as he does not fail to blow his own (?) lamp as well as his own trumpet. Again, more fresh matter in Mr. England's remarks on "wonderful and costly." In reply to this baseless insinuation, I beg to assure your readers that, as a student of science, it is not my practice to ignore the principles of dynamics; therefore I cannot say, as Mr. England has done, "that an ordinary pneumatic ball will flash several lights simultaneously, and quite as effectively." It is contrary to the experience of engineers that one pressure and one volume—and that volume and pressure being of the hand only—should overcome the resistance offered by the tubes and powder, unless a very moderate construction is put on the word "several." Then there is the questionable legality of flashing several lights from one air ball or chamber by a distributor as referred to on page 275. Probably this point will not be settled till it has cost either plaintiff or defendant a few hundreds of pounds.

Again, he uses the words, "silly remarks." That is only to divert the public who have given no attention to the chemical aspect of the subject.

Having replied to the points raised by Mr. England in his letter, I beg to thank you in advance for giving me the opportunity to defend myself, as far as I am able to do, without adding fresh matter at the risk of prolonging a discussion without benefit to your readers.—I am, yours, &c., F. W. HART.

Exchange Column.

*• No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

- Exchange oxygen generator and holder, also a Wimhurst electrical machine, for a good cabinet portrait lens.—Address, L. DIXON, Photographer, Colne.
- Wanted to exchange, 12×10 Ross' rapid symmetrical, sixteen-inch focus, for Ross' Nos. 3 and 5 portable symmetricals.—Address, 62, Stanhope-street, Birmingham.
- Wanted, ferrotype plates and mounts in exchange for interior and exterior verandah backgrounds.—Address, PHOTOGRAPHIC STUDIO, 16, Chapel-street, Edgware-road.
- Will exchange Marion's print-washing apparatus (registered), large size, for large interior background; must be good.—Address, J. DUFFUS, Queen-street, Huddersfield.
- I will exchange Ross' 8×5 rapid symmetrical and Kershaw shutter for 9×7 Optimus euryscope.—Address, G. SCHOFIELD, Cobden-chambers, Pelham-street, Nottingham.
- Wanted, a half-plate rapid rectilinear lens in exchange for half-plate camera, single lens, and double slide.—Address, W. H. STANWELL, 70, Adelaide-road, Brockley, Kent.
- Will exchange Lancaster's whole-plate International camera, with rapid rectigraph lens and stand complete, for trieycle.—Address, GATES & STARR, Mill-road, Cambridge.
- Will exchange portable developing and changing tent for good portable whole-plate camera with two or more double backs.—Address, H. S., 27, Greiffell-place, Maidenhead.
- Will exchange Dallmeyer's 2m portrait lens, background, tables, specimen frames, &c., for good pony cart and harness or live stock.—Address, D 6, 2, York-street, Covent Garden, W.C.
- Victoria camera, nine lenses, two dark slides, and two shutters, also opal glass, various sizes, offered for backgrounds or accessories.—Address, W. HUTCHINSON, 70, High-street, Islington, London.
- Will exchange a studio half-plate square box camera and half-plate portrait lens, by Mason, Glasgow, for a half or whole-plate bellows camera and lens; difference adjusted. Also exchange three backgrounds (one interior and two exterior), also eight-foot tree, in exchange for anything useful in connexion with photography.—Address, A. COOPER & Co., Photographers, Market Entry, Church-street, Inverness.

Answers to Correspondents.

*• Communications relating to Advertisements and general business affairs must be addressed to "H. GREENWOOD & Co.," 2, York-street, Covent Garden, London, W.C.

All matters for the text portion of this JOURNAL, including queries for "Answers" and "Exchanges," must be addressed to "THE EDITOR," 2, York-street, Covent Garden, London, W.C. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.

- J. J. J.—The yellow stains are produced from imperfect fixation. There is no means of removing them now.
- W. JONES.—Prepared canvas for painting on may be had in rolls of various widths from any of the artists' colourmen.
- A. CARRUTHER.—Both eosine and erythrosine can be procured from any operative chemist, or from any dealer in dyers' materials.
- J. T. LEON.—The cause of the fogging is through the plate being very much over exposed. One-fourth that given would have been ample.
- G. WILLIAMS.—Carbon tissue, readily sensitised, may be obtained from Messrs. Marion & Co., the Autotype Company, and the Woodbury Company.
- CANARY BIRD.—We are repeating your experiment with the plunge shutter, but have not as yet obtained the duplication of the image. More as to this hereafter.
- W. GILES.—Coat the inside of the vessel with paraffin wax, which will be the best. Next to this a solution of shellac in spirit. Neither will injure the developer.
- S.—Gelatine varies in price from about tenpence a pound to five or six shillings. We cannot say what you ought to pay unless we know the purpose for which the article is required.
- S. GARFIELD.—Probably it is only a solution of chloride of gold. Why not buy the salt in crystal, in tubes, from any of the dealers? You will then know what you purchase.
- D. C. L. P.—The design for the studio will do very well. The blinds and louveres will be quite sufficient to deal with the sunlight in the after part of the day. Give the roof a good slope.
- HERTS.—The marks on the negatives arise from the paper used, between the plates, in the packing. Call the makers' attention to the matter. They are evidently unaware of the effect of what they are using.
- "SCOTTY."—Unless the pyroxyline be an unusually soluble kind you will not be able to get twelve grains per ounce in solution to make an easily flowing collodion. About six grains is what is generally employed for an enamel collodion.
- B. S. J.—The only way by which you can ascertain if the picture be copyright or not, is to search the register at Stationers' Hall. The author is not bound to put "copyright" on the work. If you pirate any photograph you do it at your risk.
- GREEN FOG.—1. If the lens is genuine, and in good condition, it is very cheap at the price mentioned.—2. Any optical brass turner in London will do this work. If you fail in discovering one write again.—3. A full explanation is given in an article in the present number.

L. MINNS asks: "When was ammonia first known or discovered?"—The question is a moot one. Whether ammonia or its aqueous solution was known to antiquity is still undetermined. The manufacture of carbonate of ammonia was early known to the Hindoos.

ASSISTANT.—Different establishments have different hours for working. That these are shorter in other houses in the town is no justification for your not conforming to the rules of the one in which you are engaged, unless you stipulated for certain times when engaging. If the place does not suit you why not leave, and so avoid unpleasantness?

GIL BLAS (Glasgow).—We know nothing more of the apparatus than was contained in the article. It is evidently of German manufacture. Ordinary typographic presses are usually employed for collotype printing, and these can frequently be met with at a low price, second-hand. If you have all the works you name you have all that is published on the subject. With them you ought, with practice, to work the process to a successful issue.

F. R. M. S. writes: "Can any reader give me a list of good subjects for the camera within a radius of eight or ten miles of Whitby?" He also asks: "What is the advantage or otherwise of using (say) a 10×8 landscape lens for half-plate pictures?"—In reply: One advantage will be that the plate will be covered sharp to the edge with a larger stop than would be necessary to impart an equal degree of sharpness to the edges of the 10×8 plate.

R. BRAYLEY writes: "I have during the winter been making my own dry plates, and have by me a lot of spoilt emulsion, probably a couple of gallons or more in all. Is there any less troublesome plan of recovering the silver from it than boiling it with potash?"—The simplest way of recovering the silver is to melt the emulsion and then add sulphuric acid, in the proportion of three or four ounces to the pint, and well stir from time to time. If the emulsion be now allowed to rest for a day or two the bromide will settle to the bottom in a compact mass, when the supernatant fluid can be poured off. A large vessel should be used, as the addition of the acid causes violent ebullition.

S. E. P. puts the following queries: "1. What are the advantages of registering photographs and the price?—2. Does registering confer copyright?—3. What is cost of copyrighting? also, is there any book published on copyright law re photographs?—4. If one's photographs, portrait or landscape, are not copyrighted, can any other photographer copy them with impunity?"—In reply: 1. The advantage is to secure the copyright to the author.—2. Certainly, if done according to the Copyright Acts.—3. The cost of registering is one shilling, and a trifle extra for the form. Our publishers will effect the registration for you if you send them a picture, together with a postal order for one and sixpence. The Act of Parliament itself on copyright in works of fine art and photographs can be had for a few pence from the Queen's Printers, Messrs. Spottiswoode & Co.—4. Yes.

T. MOORE writes as follows: "A friend of mine has a French lens which he asserts gives better detail in the picture when it is worked with the full aperture than when it is stopped down. Is it possible that this can be the case? I have always understood that stopping down must improve the definition of any lens, and here it is said to impair it."—As a rule, a diaphragm improves the definition, but it does not follow that it does always. For example, if the centre of the lens be defective and a stop be inserted, only that portion is used; but when the instrument is used with the full aperture the best portions are also brought into play, and, to some extent, ameliorate the defective part. We recently had to examine such a lens; with the full opening the definition was moderately good, but as it was stopped down it gradually became impaired. A close inspection disclosed a mass of striae just in the centre of one of the glasses, which fully accounted for the impaired definition.

N. LAWRIE says that he is continually reading that some of the old photographs produced twenty or thirty years ago, and toned and fixed in the same bath, and which received but slight washing, are still as good as ever. He asks, if this be the case, why photographers do not go back to the old system of working, for, he says, no silver prints produced at the present time will last anything like so long.—One very good reason why the old system would not do nowadays is the fact that neither the negatives now taken nor the papers now in the market are suited to that method of toning. In the old days the paper was both strongly salted and highly sensitised, sometimes a hundred-and-twenty-grain silver bath being used. The negatives, also, were very intense, and had to be deeply printed. It was this that conduced to the permanency—not the system of toning, which more frequently than not was sulphur toning pure and simple. To produce good prints by the old method, strong negatives and highly sensitised paper are essential—things not general at the present day.

THE "granitine dishes" of Messrs. Taylor, Tunnicliff, & Co., of Hanley, are now becoming well known. Samples of these are before us, and with these this firm has enclosed fractured pieces made both of their granitine ware and also of the earthenware of which the ordinary dishes so long in the market have been made. The difference between these is most marked. The latter is so porous that when the tongue is applied to the fracture it adheres, whereas the granitine is close-grained, hard, and non-absorbent.

No. 1515. VOL. XXXVI.—MAY 17, 1889.

AN IMPROVED PHOTOGRAPHIC LENS.

Among the specifications of patents published in our columns to-day will be found one on a new photographic lens.

Previous to entering upon a description of it, we may observe that the external surfaces of a lens do not afford an adequate clue to its powers. In this connexion and by way of illustration we may remark that we possess two moderately thick pieces of glass, the surfaces of which are absolutely flat, as if both had been cut out of a piece of rather thick plate glass; and yet when looked through one of them magnifies and the other diminishes any object examined. This proves a puzzle to most people, but all mystery ceases when we state that the seemingly plain plate of glass is in reality formed of two pieces cemented together, the junction being curved surfaces, being thus a plano-convex and a plano-concave lens united. But each of these elementary parts differs from the other, one being formed of glass having a high and the other a low degree of refraction—respectively a dense flint and a light plate glass. According to whether the one or the other is the most highly refracting so is the completed piece either a diminishing or a magnifying glass.

Turn we now to the new lens patented by Messrs. Schröder and Stuart. It will be seen from the specification that as the external radii of each lens in the combination are measured from a common centre, the lens would of necessity be a negative or diminishing one if formed of one homogeneous piece of glass, its form being essentially concave, or, more correctly, a negative meniscus. Parallel rays falling upon such a lens would diverge after transmission, and would therefore be useless as a photographic objective whose function is to bring to a focus all light incident upon it. And yet the patentees have so managed, by a suitable selection and arrangement of the components of this, externally speaking, negative lens, to make it a positive one capable of giving an image. The doing so would have been quite impossible—that is, as far as photographic utility is concerned—but for the introduction of the new Jena optical glass; but by its agency many optical problems which in the old flint and crown period could never have been solved are now capable of solution.

The new lens is, as we have said, a concave meniscus, the concave surface being of shorter radius than that of the convex. Its construction may briefly be summed up as follows:—It is composed of two simple lenses, a plano-convex formed of glass of a *high refractive* index and *low dispersive* power, cemented to a plano-concave of a lower refractive index but of the same or preferably of a higher dispersive power, the two flat surfaces being of course united by cement.

The lens thus briefly described may be used either singly as

a landscape objective or in combination with another of similar construction, in which case they must be set rather closely together, concave sides next each other, with a diaphragm between. Thus constructed it will serve as an architectural or copying lens, as there will be no distortion.

But whether as a single or a combination objective it ought, we think, to give such elongation, coupled with excellence, of the oblique pencils as to yield a flat field with good marginal sharpness.

Scientific men or those interested in the details of construction and the properties of the glass necessitated in its manufacture will find the requisite information in the specification of patent on another page.

THE DEVELOPMENT OF TRANSPARENCIES.

In employing pyro for this purpose, we think there can be no possible question as to the desirability or otherwise of combining it with sulphite of soda, since the absolute necessity for preserving the purity of the lights almost compels it. It is quite true that under extremely favourable circumstances pyro alone may be used without any derogation of the integrity of the result, and that clearing solutions may be used to remove any stain that may arise, but the percentage of successful transparencies so produced is very small. We may therefore start with the understanding that some form of "sulpho-pyrogallol" is to be employed.

This, of course, refers to gelatine plates, for with collodion the tendency to stain is absent, but even here the sulphite is no disadvantage since it can be made to materially modify the tone of the image.

For the purpose nothing answers better than the ordinary "ten per cent." solution of pyro, made by dissolving forty-eight grains of that substance in cold saturated solution of sodium sulphite to make up one ounce. Each ten minims of the solution then contain one grain of pyro. We have also seen some very pleasing tones produced upon gelatine plates, where the colour has been attributed to the use of meta-bisulphite of potash. If this salt be used its proportion may be varied to the extent of from one to two grains to each grain of pyro; but due allowance will have to be made in adding the alkali for the free acid it contains.

Equally important as regards the colour given is the choice of alkali. With very many operators, no doubt, liquor ammonia remains still the favourite, at least in conjunction with pyro, though there is undoubtedly a growing tendency to employ the carbonates, a practice which we are strongly inclined to favour for transparency work on account of the great

cleanliness of working thus secured. If ammonia be used the usual stock solution, made by diluting one volume of the strong *liquor* with water to three volumes, will answer.

If a carbonate be preferred, we should strongly recommend on many grounds the potassium salt.

Not only is the character of image produced as regards both purity and tone superior to that given by soda or ammonia, but the salt is a more convenient one to employ than either of the others, being easily obtained of definite composition and purity. The same can scarcely be said of sodium carbonate as usually employed in the form of washing soda, though by using the pure crystals or the anhydrous powder a nearer approach to accuracy is obtained. Carbonate of potash is very deliquescent, but only requires thorough drying to restore it to the anhydrous condition. Carbonate of soda, on the contrary, when it absorbs water requires to be "ignited" or heated to redness before the water can be completely expelled. The crystals of the latter salt, though originally containing a definite quantity of water, are liable to variation from efflorescence or loss of a portion of their water of crystallisation. Carbonate of ammonia is a very unstable compound, and not to be recommended on that account.

Carbonate of soda has an unpleasant tendency, even when combined with sulphite of soda, to impart a strong yellow tinge to the gelatine film, which, objectionable enough in a negative, totally ruins a transparency. Curiously, this yellow colour is frequently not apparent on the completion of development, but makes its appearance after washing, and is entirely unaffected by any clearing solution, or if it be removeable by such means, returns when the film is washed. For this reason alone we should eschew carbonate of soda and rely for preference upon carbonate of potash.

The strength of the solution that may be conveniently employed, calculated in terms of approximately equal energy, according to the table published in our ALMANAC for 1885, will be carbonate of soda (cryst.), 50 grains, or anhydrous, 18 grains to the ounce; carbonate of ammonia, 16 grains to the ounce, and carbonate of potash, 24 grains. These will prove convenient strengths for diluting with an equal bulk of pyro solution for use.

A certain proportion of restraining bromide is a *sine quâ non*; this may conveniently, and for transparency work perhaps preferably, be combined with the alkali, instead of being kept in separate solution. Ten grains of bromide of potassium to each ounce of alkali solution will be found a suitable strength.

For actual use the pyro solution may be diluted according to the quantity required to the strength of three grains to the ounce, and for normal exposures, if this be mixed with an equal volume of alkali solution, it will be found quite strong enough for most plates. If ammonia be the alkali, the concentrated solution mentioned above must be added in the proportion of six minims to an ounce of water, and mixed with an equal quantity of pyro solution.

The components of the normal developer will therefore consist in each ounce of—

Pyro.....	1½ grains.
Bromide of potassium.....	5 "
Strong ammonia.....	1 minim.
Or, Carbonate of soda (cryst.).....	25 grains.
" " (anhyd.).....	9 "
" potash.....	12 "
" ammonia.....	8 "

As has been already fully stated, we do not calculate or allow

for any latitude in development, but should slight errors in exposure be apparent, the developer may be modified by using more pyro or more alkali according to whether the time has been too long or too short.

In substituting hydroquinone for pyro it may be dissolved in the proportion of sixteen grains to the ounce of water, together with one drachm of sulphite of soda. The latter acts powerfully as a retarder of development, but is not otherwise objectionable in lengthening the exposure necessary; it is not used for the purpose of preventing stain, but merely to improve the tone.

If quicker development be desired the alkaline solution may consist of five grains of sodium hydrate or eight grains of potassium hydrate, with twenty grains of bromide of potassium to each ounce of water—this to be mixed in equal parts with the pyro solution.

If ferrous oxalate is to be used, though we see no benefit to be derived from such a course, it should be as concentrated and as freshly mixed as possible, but rendered decidedly acid, and well-restrained with bromide. A developer restrained, or with its energy reduced by simple dilution, is of no use. The best formula is the original one, in which precipitated oxalate of iron is dissolved in hot saturated solution of oxalate of potash. When cold, one minim of sulphuric acid and three grains of bromide are added to each ounce.

THE EFFECT OF REVERSING LANDSCAPE LENSES.

ARISING out of a paper on "Single Lenses," read by Mr. T. R. Dallmeyer on Tuesday evening at the meeting of the Photographic Society of Great Britain, was the question of the effect produced by reversing the usual position of the landscape objective. A case was cited in which a photographer, who had failed in obtaining the required sharpness when taking a portrait by such a lens used in the ordinary manner, secured all the definition he desired by the expedient of reversing it. No explanation as to the reason for this having then been given, we take occasion, in a necessarily off-hand manner, to make some observations relative to this subject.

If a lens of plano-convex or slightly meniscus form (that commonly employed for landscape lenses) have its flattest side directed towards the view without any diaphragm or other obstruction in its tube, the image on the focussing screen will be found to be hazy, and by no amount of racking it in and out can sharpness be obtained. But if, under the same conditions of full aperture, its position is reversed, and the convex side be directed towards the subject, then does the sharpness become considerably increased, especially in the centre of the field. Indeed, some single lenses give such a high degree of sharpness when thus used that the employment of a diaphragm fails to impart greater definition, although by such a diaphragm is the area of definition extended.

The reason for this is to be found in the fact that spherical aberration is minimised when the convex surface of a plano-convex lens receives the incident rays and transmits them axially; whereas by the same lens, when the flat side is outwards, spherical aberration is at its maximum: hence, while there is illumination everywhere there is sharpness nowhere.

If the lens be of an extremely deep or pronounced meniscus character, such as obtains in either front or back of a wide-angle doublet, then when the convex surface is outwards no good definition can be obtained unless a diaphragm be inter-

posed between the lens and the ground glass, rather close to the former. With high defining power under the altered conditions we also obtain a large area of sharpness and fair flatness of field; whereas by reversing the position of the lens, its diaphragm being now outside, the quality of the definition is impaired, although the sharpness, such as it is, will be found more evenly distributed all over the plate.

Several practical deductions may be made from the foregoing. One only shall claim attention at present. When using a doublet composed of lenses of a pronounced meniscus form, and when occasion arises to render the employment of only one of them desirable (as when taking a view of a subject at a distance on a larger scale), it is not absolutely necessary to remove the front and use the back lens alone as frequently recommended, for it may prove to be more advantageous to remove the back and leave the front *in situ*. Many cameras will not extend to a length sufficient to permit of the former arrangement being adopted, for be it remembered that the optical centre of a meniscus lens—that from which the focus is measured—is situated a short distance outside the convex surface, and this, in the case of an objective whose components are separated to the extent of one to two inches, makes a difference somewhat exceeding this in the expansion of the camera.

The more a lens partakes of the plano-convex form, as in the case of the front lens of a portrait combination, the less proportionate area of sharpness will be obtained when using it alone, convex side to the subject, although near the axis the sharpness with even a large aperture will be all that is desired.

THE ill-fated Cellerier Syndicate, or Photographic Company, which made such a noise in the financial world but a comparatively short time since, has now paid the debt of nature. Its remains have brought the sum of two hundred pounds, which, after the expenses incident upon the winding up are paid, will leave but little to divide among the shareholders.

At last there seems to be some prospect of this country possessing a National Portrait Gallery. When the building is obtained—and for which, by the way, we shall have to thank a private individual—it is to be hoped that a section of it will be devoted to photographic portraiture. Many who have distinguished themselves, and whose portraits would be prized by their country, have never sat for an oil painting, or, if they have, the portrait, as a work of art, may not be such as would be considered worthy of a place in a national collection of pictures. Nowadays it is rare indeed that any one has not had his portrait taken by photography. A photograph may generally be taken as being far more truthful as a likeness than are a large proportion of the oil paintings.

It would be a great pity if the portrait of an individual who had rendered himself famous should be lost to the world simply because it existed only as a photograph. Any photograph can be enlarged, and, in the hands of a skilful artist, made into a fairly good picture without alteration of the likeness. And this can be done by processes which yield results which are quite as permanent as oil paintings. For example: Why should not the portraits of those distinguished scientific men shown in the science and art department, South Kensington, and which are now fast fading, be reproduced before the fading has gone too far and find a place in the national collection? It is quite possible that there is not an oil painting of the majority of them in existence, or if there were the family may prize it too highly to let it out of their possession. If the likeness be the chief consideration in a national collection of portraits, then photography will take the palm. But if pictures or works of art are to be the principle

feature the matter may possibly be different. The donor of the proposed building might possibly be approached on this subject.

AN ounce bottle of pyrogallie acid, it was stated at one of our meetings the other evening, is often a very indefinite quantity. It was not, even for a moment, insinuated that short weight was ever intentionally supplied. Indeed, it was mentioned that more often than not the bottles contained over the prescribed quantity, and that sometimes to a considerable extent. The prevailing idea was, that as "pyro" is troublesome to weigh, and is now very cheap, the bottlers adopt guess work as their standard, and err on the side of giving too much rather than too little.

Few, it may be presumed, take it as a grievance to receive more than they pay for; but sometimes over weight may prove an inconvenience and lead to trouble. As we have said, pyrogallie acid is troublesome to weigh, therefore it is the custom with most persons, in making up their stock developing solutions, to dissolve the whole of the bottle at once, taking it for granted that it contains an ounce, neither more nor less. Indeed, we have seen formulae written, "When dissolved pour into an ounce bottle of pyro and make up to," &c. Now it is clear that if one bottle contains, say, twenty per cent. more than the prescribed four hundred and thirty-seven and a half grains—and at the meeting referred to a much larger excess than this was spoken of—and another contains the exact quantity, or may be something less, the resulting developers would behave differently. If two such developers happen to be employed in testing different brands of plates they might act prejudicially to the one or the other. A difference of twenty or thirty per cent. in the pyrogallie acid in a developer is important. A skilled operator might not be misled, but in the case of a beginner the case might be different. Moral: Weigh your pyro, and do not take the contents of an ounce bottle as being a standard quantity.

ONCE upon a time, when photography was young, pyrogallie acid was quoted at four shillings per drachm. At that time the vendors were never, that we remember, charged with giving over weight. By the way, the four shillings per drachm article in those days could not be compared, for quality, with the one shilling per ounce one of the present time. If such an article as the old one were now offered, even at a few pence per ounce, we doubt much if it would find purchasers. Instead of being of a snowy white it was more or less brown or yellow, and its developing energy was about on a par with its, according to present ideas, unsightly appearance.

SHOR windows are a trying ordeal for photographs to be exposed to when they are not properly fixed, as the strong light very soon causes an ugly discolouration. A few days back we noticed the vignette portrait of a well-known celebrity exhibited for sale in a stationer's shop window, which was but partially fixed by the "hypo"—probably through its being allowed to remain in contact with other prints while in the bath—and it had suffered badly from the exposure. The print bore the name of a well-known house, and it had clearly not been long issued. The operation of fixing prints does not require skilled labour, therefore it is too frequently intrusted to lads or girls without proper supervision, hence the employer's reputation often has to suffer.

SPRING is with us now in earnest, and the country, generally, is in a charming condition for photography, while the light, actinically, may now be considered at its zenith. Far less exposure is required now than will be necessary later on—say in July, when the light to the eye may appear more brilliant. Then, it must be borne in mind, the foliage will be of a much more non-actinic character than it is at present. These facts should be remembered by the novice, for one of the greatest faults with the majority of beginners' negatives is under exposure.

THIS is an excellent time, our readers may be reminded, for instantaneous work, on account of the highly actinic quality of the light.

Many instantaneous pictures of cattle in which foliage is included are spoiled by the latter being too heavy through insufficient exposure. If such pictures be taken at this season much of this may be avoided, owing to the actinic value of the foliage coupled with the enhanced quality of the light. Stereoscopic pictures of cattle, taken instantaneously, with a landscape background, are very charming. Instantaneous stereoscopic photography is a branch of the art we should like to see more popular than it appears to be as yet.

How ideas and fashions change! At one time amateur photographers were by no means proud to be seen travelling with their apparatus. Consequently, many attempts were made to disguise it, particularly the camera stand. This was sometimes made up as fishing tackle, or perhaps as an alpen stock, or other popular article. An umbrella camera stand, or rather a camera stand disguised as an umbrella, was also contrived, as well as other devices, for its concealment. Nowadays amateurs, both male and female, appear to be proud rather than otherwise of their apparatus. Carrying a camera stand openly appears to be quite as fashionable as carrying a tennis racquet and a pair of tennis shoes, and this is saying something.

ECHOES.

LANTERN plates at a cost "for material"—i.e., for emulsion—of one halfpenny per dozen! The mere suggestion raises visions of the fabulous profits of the plate makers, who even at a shilling a-dozen have a margin of elevenpence halfpenny out of which to pay for glass, labour, &c., and still leave a handsome percentage for themselves if they only go the right way to work.

Or, on the other hand, we may dream of the immense quantities of silver that are absolutely wasted, lost to the world in fact, in the course of a year, under the present system of manufacture; for how many of the users of lantern plates nowadays take the trouble of recovering their wastes, even when as rich in silver as the fixing bath? All that silver finds its way into the sewers, and thence to the ocean, or on to some sewage farm, in either of which resting places it will have to remain for countless ages before it accumulates in sufficient quantity to again attract the notice of man.

That an unnecessarily large quantity of silver is, as a rule, introduced into dry plate films—unnecessary, that is, in the actual formation of the image—may perhaps be taken for granted; but it saves trouble in other directions, and hence the practice prevails. Still, there seems to be a very wide difference between Mr. Starnes's proportions and those in general use. It may be remembered that in the earlier days of gelatine emulsion—the comparatively "slow" days—ten or a dozen grains of silver nitrate to the ounce were considered ample, but as rapidity increased, and "boiling" and "ammonia" methods were adopted in the manufacture, the quantity rapidly rose to twenty grains, or even more, to each ounce. It would be an interesting experiment to take, say, a hundred negatives, of fairly average subjects as regards light and shadow, and, having extracted the silver forming the images, compare it with the quantity contained in the films before exposure, which might be readily ascertained. I dare say the result would be surprising to many.

I am quite of Mr. Starnes's opinion that quality depends more upon the manner of forming the silver haloid than on its quantity; that, in fact, is open to very easy demonstration. But I do not agree with him quite when he quotes the "much better results" of collodion-bromide as evidence in favour of his theory of fineness of division. The latter, I grant, is a desirable, if not absolutely essential, quality in a lantern plate; but collodion-bromide, and, for that matter, wet collodion plates, owe the preference given to them for lantern slides to their clearness, non-liability to stain, and to the facility with which a variety of tones may be obtained. Fineness of division is not an element that enters into the question there, or iron-developed wet collodion plates would be out of the hunt. Besides, it is possible to form just as fine an emulsion in gelatine as in collodion, but it does not follow that equal results can be obtained in both cases.

Dr. Paul has expressed himself before the Liverpool Amateur Photographic Association in rather depreciatory terms regarding

what he terms "micro-photography," meaning, however, what I thought it had long been agreed to call "photo-micrography." Its value he thought had been exaggerated; that, though invaluable for low powers, with high powers he preferred to make drawings. The first point that strikes me in connexion with Dr. Paul's view is, that it is not every microscopist who possesses the requisite skill with the pencil to make drawings, and if he did there still remains to be considered his individual capacity for accurate observation. By means of photography it is true it is quite possible to thoroughly misrepresent the object photographed, still I cannot help thinking that it is easier to make a good photographic copyist than a good draughtsman. In other words, the trouble involved in learning to make good and reliable photo-micrographs is infinitely less than that necessary to the production of equally accurate and reliable hand drawings.

The photographic work with high and low powers respectively presents very different degrees of difficulty, which is not the case to the same extent with the pencil. In Dr. Paul's case it may be that he, a practised observer and skilled draughtsman, may find it more to his purpose to continue to make drawings than to photograph the objects with high powers; but the circumstances would be different, I venture to think, in the majority of cases—my own I can certainly vouch for.

The exigencies of space in reporting scientific proceedings sometimes lead to ludicrous results. The reporter in trying to squeeze a great deal of "high" science into a few lines perhaps does not quite catch the meaning of the lecturer if the latter even himself express it. Thus Mr. Friese Greene's attempt to adapt Sir Humphry Davy's electro-chemical theory to photography, mixed up as it is with several "suppositions" of his own, reads very funnily in the report, and I am sorry to say I was not at Bath to hear exactly what he had to say.

In the published specification of a recently patented "detective" camera I find it stated that the "means of focussing by means of an oblique mirror was adapted" (query adopted) "many years ago by a Mr. Sutton." I am compelled to pause before going into the merits of the invention to take breath. A Mr. Sutton! I only know, or rather have only known one, and I have a fairly good recollection, personal and otherwise, of past photographic history.

Leaving one or two earlier names unnoticed, we have about fifty years ago a Monsieur Daguerre and a Mr. Talbot almost simultaneously introducing processes which brought photography within the bounds of practical utility, and their methods served generally for portrait and landscape work respectively, until a Mr. Archer introduced his collodion process. Then a great number of scientific men of all sorts arrayed themselves in the ranks of photographic experiment, to many of whose names it would be supremely ridiculous to attach the indefinite article. Amongst the number was a Mr. Thomas Sutton, who is, or was, the Mr. Sutton of the Patent Office specification.

If the late Thomas Sutton, one of the earliest workers in and writers on photography, the editor, or part editor, of at least three photographic journals, one of which is still in full life, and the immediate successor to a Professor Hardwich (also still alive, fortunately) as professor of photography at King's College, if such a man, who died in photographic harness not so very many years ago, is to be, in memory, at the mercy of a modern adaptor of his ideas, to be described as a Mr. Sutton, it behoves us who still live to make provision for our tombstones. Truly may I say with Rip Van Winkle, "How soon we are forgotten." In only a half sense can I requote, "*stat nominis umbra*."

However, the camera patented by a Mr. — but no! I do not wish unnecessarily either to call attention to his individuality or to advertise his patent. I will say the idea now utilised and adapted to detective camera purposes is a very good one, and goes beyond the intention of Mr. Sutton, who, if I recollect rightly, put it forward simply as a matter of convenience, to obviate the necessity for stooping so low in focussing when using a low studio stand.

But its first application to "detective" cameras—not then so called—was shown to me quite ten years ago by a distinguished F.R.S., who having experienced the difficulty of catching moving objects on the proper part of the plate had devised the means by which he could watch and follow his object until at the right instant he released the trigger and the picture was taken. From my recollection of the ten-

year-old arrangement it was better than I can make out the modern patent to be from mere reading; and I have heard of, but not seen, another "detective" camera of American origin, in which the same principle of exposure is involved. So the Mr. Sutton's stationary mirror has proved useful to at least three later inventors. JUNIUS.

THE PRESERVATION OF SOLUTIONS OF PYROGALLOL.

THERE seems to be an impression abroad that certain substances exercise a "preserving influence" on whatever is brought in contact with them. The idea, although unscientific, is not without foundation. A grain or two of corrosive sublimate added to a solution of gum or other putrescible liquid will make it keep indefinitely, although the mercuric chloride forms no sort of chemical compound with the gum. The explanation in this case is not very far to seek. The gum is rendered poisonous by the addition, and so becomes unfit to support the life of the organisms which cause fermentation. In the case of pyrogallol, however, we are not dealing with the complicated phenomena attending the life even of the most minute of organisms, but with a case of direct oxidation by contact with the air. We might naturally suppose, then, that the problem of preserving pyrogallol solutions, if solvable, should be quite simple. Such, however, is far from being the case, as every photographer knows to his cost. The experiments I am about to describe, although I cannot claim that they afford a full solution of the problem, do, I think, throw some light on it, and indicate with sufficient clearness the classes of substances which prevent and which assist the oxidation and destruction of pyrogallol solutions.

The following experiments were all performed at the same time, and under as nearly as possible the same conditions. In all cases where the strength is not referred to the solution was the same, that is, a one per cent. solution (roughly speaking four and a half grains per ounce). This was made with the pyro from a freshly opened bottle, and well-boiled distilled water, which had been allowed to cool in a closed flask. Prepared in this way, pyro solution is perfectly clear and bright, with no more colour than the water used in making it, a high testimony to the purity of Messrs. Schering's preparation. Equal volumes of the solution prepared as described were placed in a number of little flasks, the various substances to be experimented on added in small quantities, and the changes which occurred observed daily for seven days. It is difficult to arrange a set of experiments of this sort in any definite order, but they may be classed roughly under three heads: (1), Those in which the addition had a distinct effect in hastening oxidation; (2), Those in which there was no marked effect; and (3), Those in which there appeared to be a greater or less preservative effect. The first class include all the basic substances tried and a few neutral salts.

Caustic potash, soda, and ammonia.—The effects of these on pyrogallol solutions are so well known as to require no description. The solution in each case turned brown from the surface in a few minutes.

Calcium and barium hydrate.—Both cause rapid oxidation, but the appearances produced are remarkable. When lime water is poured into the one per cent. pyro solution a beautiful violet colour appears, but vanishes again almost instantly, the liquid turning of a dirty brown, then lightening to yellow; on further addition of lime water the colour flashes out again, or it may be temporarily restored by shaking the solution with air. The violet substance is evidently one of the many possible oxidation products of calcium pyrogallate, but so far as my experiments went I could not succeed in keeping the violet solution for more than a few seconds, either when exposed to the air or enclosed in a perfectly filled flask. Baryta shows some tendency to behave in the same manner as lime, but the liquid soon becomes filled with a black precipitate.

Carbonates of potassium, sodium, and ammonium act in much the same way as the caustic alkalis, but more slowly; a brown colour gradually spreading down into the solution from the surface.

Bichromates of potassium and sodium.—Effects very similar to those of the carbonates, but much slower.

Carbonates of calcium and barium.—These are, of course, added as insoluble powders and produce no change for some time. After a quarter of an hour the liquids were yellow. After fifteen hours the contents of the flasks had become of a turbid dark brown, showing traces of colours similar to those obtained with calcium and barium hydrate. These effects are remarkable, as they seem to indicate that pyrogallol, although not technically an acid, is in reality a sufficiently strong acid to decompose carbonates very slowly. No effervescence was in any case visible in making up these mixtures.

Hydroxides of zinc and iron.—These were prepared at the time,

thoroughly washed, and added in the moist state. The mixture to which the iron was added turned inky black in a very short time; that with zinc turned yellow in a few minutes; by the next day a black scum had formed on the surface, but the rest was nearly white. The whole turned dirty grey on shaking.

Sodium hyposulphite showed no rapid change, but after fifteen hours the liquid was dark brown.

Potassium bichromate.—This is one of the most curious of all the reactions. Bichromates being strong oxidising agents we might expect them to act quickly on pyrogallol solutions. Such is the case; but the action is evidently not a simple oxidation. The mixture turns dark red almost the moment it is made up, and turns rapidly darker till it is nearly black. After fifteen hours the flask contained a soft black jelly, which changed no further on keeping.

All the substances mentioned above, except the last two, are either bases or carbonates, and all bring the pyrogallol into a state in which it readily absorbs oxygen and is destroyed: in a word, form pyrogallates; and these, not the so-called pyrogallic acid itself, are strong reducing agents.

Each experiment above described was thrown aside as soon as it had given a decided answer to the question under examination. Indeed, it was only, as the Highlander said, "for the conceit of the thing," or for completeness, that I performed the experiments described with the caustic alkalis, for we all know very well how quickly alkaline pyrogallates are destroyed by the air.

The next series of experiments are those in which the addition had no rapid deleterious effect on the pyrogallol. The substances here dealt with are, for the most part, salts—ammonium bromide, chloride, and acetate. They all acted in very much the same manner, hastening the oxidation and colouring of the solution to a quite perceptible extent. These mixtures were all yellow after fifteen hours, and dark yellow after seven days, but the change was very far from being complete at the end of this time.

Potassium nitrate hastened the oxidation more than the salts mentioned above. It is difficult to believe that pyrogallol can reduce a nitrate to a nitrite, yet this seems the only simple explanation of the facts. This solution showed perceptible colour in a quarter of an hour, and was brown and turbid after seven days.

Sodium sulphate and acetate.—The former of these salts was comparatively indifferent, showed no change in fifteen minutes, became yellow after fifteen hours, and then changed very gradually to a colour similar to that produced by ammonium bromide. The acetate has a stronger action, the liquid being yellow after one day, and brown and turbid after seven days.

I now come to the only two acid substances which were found to have a bad effect, namely, alum and nitric acid. Alum, although a salt (double sulphate), has an acid reaction to test paper, and I naturally expected that it would be more or less effective as a preservative; such, however, was not the case, as the solution turned first of a curious pinkish colour, and in seven days was dirty brown. Nitric acid being a very strong oxidising agent, I naturally anticipated that it would quickly give up its oxygen to the pyrogallol. Such is the case, the solution turning yellow throughout on adding the acid; but further, the acid appeared to aid the continuous oxidation of the pyro by the air. If the nitric acid is reduced to nitrous during the reaction, this would absorb oxygen from the air and then be again reduced, and so act as a carrier of oxygen. It is only fair to say that in this experiment I used a larger proportion of nitric acid than would be employed in any photographic solution; it is not at all impossible that a very small quantity might have quite different effects. Taking the various experiments in the order of the keeping quality of the mixture, this always improving as we go on, the next on the list is plain solution of pyro, with no addition whatever. This solution keeps better than any of those mentioned above. It showed no trace of colour in a quarter of an hour; after fifteen hours was, so far as one could distinguish, the same as the mixtures with ammonia salts, sodium sulphate, &c. After seven days, however, it had a much lighter colour than any of these. A very concentrated solution (perhaps twenty per cent.) was made up at the same time as the others and kept along with them. It turned a little darker than the one per cent. solution, although probably the proportion of the pyro contained in it which suffered change was much less. So it is shown again, as it was shown long ago, that pyro solutions may very well be kept without any preservative. A strong solution kept in an ordinary corked bottle will certainly not lose strength perceptibly for months. Some of the original solution was kept for comparison in a flask filled completely, so as not even to leave an air-bubble, and then tightly corked. Strange to say, it did not remain perfectly colourless, although it was so when first put up; it gradually acquired a very slight yellow tint, fainter, however, than that of most of the mixtures now to be described.

The last class of substances to claim attention are really by far the most important from the point of view of the photographer, namely, the preservatives; these are, with one exception, acids. For no reason which I can assign, potassium sulphate seems to have a beneficial effect, though in a much less degree than the acids. Acetic, citric, and tartaric acids all act as nearly as possible in the same manner. After a quarter of an hour the flasks had a perceptible yellow colour, which deepened very slowly, and remained after seven days much lighter than the solution without addition.

Hydrochloric acid is more effective than any of the organic acids tried, and occupies a position intermediate between them and the other strong mineral acids. The solution containing hydrochloric acid acquired a curious pinkish-brown colour, changing very slowly.

Sulphuric and sulphurous acids and potassium bisulphate.—Of all the mixtures tried these three were the only ones which remained perfectly colourless after seven days. The sulphurous acid used was old and contained much sulphuric. The result of all these experiments then is to point out sulphuric acid as unquestionably the best preservative for pyrogallol solutions.

In conclusion, I may summarise all these results by forming a list of all the substances experimented with, in the reverse order from that followed above, taking the best preservative first, and the most quickly destructive solution last. Sulphuric acid (and sulphurous?), potassium bisulphate; hydrochloric, citric, tartaric, and acetic acids; potassium sulphate, solution without addition; sodium sulphate; ammonium bromide, chloride, and acetate; sodium acetate; nitric acid; potassium nitrate; alum; sodium hyposulphite; carbonates of calcium and barium; hydroxides of zinc and iron; bicarbonates of potassium and sodium; carbonates of potassium, sodium, and ammonium; calcium hydrate (lime water); barium hydrate; ammonia, caustic soda, and potash; potassium bichromate.

COSMO I. BURTON.

ENLARGING METHODS.

III.

THE kind of negative most suitable for enlarging requires some consideration. The prime qualities are sharpness and freedom from granulation, fog and density being secondary evils, capable of being modified or removed by one or other method of making the enlargement, whereas a general want of definition and granulation, almost amounting to rottenness, are beyond the operator's power to correct. These defects have to take their chance, and as they are now extremely common, they do much towards settling the argument of direct work *versus* enlargements, to the detriment of the latter. Comparisons under such circumstances are unfair and odious. I am no advocate for microscopic and map-like definition at the expense of more artistic qualities, at the same time photographs in the texture of a cross between cotton-wool and "macadam" are not to my liking.

Of late years we have been going decidedly backwards in respect of these qualities, the loss or its aggravation in some cases being ascribable to the employment of the cheap and inferior kinds of lenses with which the market is flooded, and which appear to find their way into the hands of photographers of the better sort, and mainly to the rage for great rapidity, whether necessary or not, to which the bulk of the craft elect to sacrifice the refinements of the older processes. Any old-established photographer of the first class who possesses the negatives of his thirty years or more of practice will have no difficulty in instituting comparisons and deciding as to the extent of the gain or loss in these respects in the practice of modern photography. Probably his series will include negatives by iodised collodion and pyro development, bromo-iodised collodion developed with weak and strong solutions of iron, and iron restrained by colloid bodies, as well as samples of negatives by dry processes, whose preservatives included almost the whole of the stock-in-trade of the grocer and brewer, collodio-bromide emulsions and alkaline development, possibly a few transparencies by the albumen process, and so forth, till the era of gelatine is reached, when he will find specimens in all the colours of the rainbow and plenty of a gritty look. The deposit of some of these earlier kinds partook more of the character of a stain, being so exceedingly fine and structureless that it would bear magnification to almost any extent. Take, for instance, the better kinds of micro-photographs that had a "run" many years ago. I recollect having a series by Mr. Dancer, I believe, through my hands, which were truly marvellous in this respect, some of the specimens being from line engravings and quite free from rottenness when viewed with a high power. Deposits of this description were capable of receiving the well-defined impressions of the best lenses without loss, and of enlargement to considerable

dimensions before the defects of granularity and woolliness became sufficiently apparent to proclaim the product as an enlargement.

The best specimens of dry-plate work of the older types, or, in fact, of any in respect of these qualities which have ever come under my notice, belonged to the late Mr. Daintree, agent-general for Queensland. A series of his negatives were in my possession for the production of stereoscopic and lantern transparencies about twenty years ago, and in course of conversation with him he told me how they were produced and under what circumstances. They had been taken some years previously during his exploring expeditions, the plates being prepared by himself frequently while leading a nomadic life far away from the centres of civilisation. They were by a collodion process preserved with a diluted alcoholic solution of one of the gums of the *Eucalyptus*, which he styled "bloodwood gum resin." I believe he published his process early in the seventies. It was simple, and must have been fairly rapid, for groups of animals and natives were among his subjects. Three or four years subsequently I wrote to him for a sample of the gum, he, however, had not any, but very kindly gave me a reference to Mr. Hill, the government botanist of Queensland, who as kindly and promptly responded to my request by sending me some, a part of which I have now in my possession. The negatives had the appearance of having been produced by an albumen process, so fine and structureless was their character.

In the course of business, negatives of all descriptions and by many processes find their way to Littlehampton, either for enlargement, reduction, or to be reproduced reversed for photo-mechanical work—so opportunities of comparison I find neither few nor far between. A striking instance occurred recently. The parcel contained a quarter and two half-plate negatives, from which others were to be made of a uniform size of 15×12. The quarter was a good specimen of wet plate, the halves, respectively, were ditto of slow and rapid gelatine plates. Transparencies were made from each in the usual way and by the same means, from which the negatives were made immediately following one another: that from the quarter being of splendid quality and equal to any original of the size; the slow gelatine coming next, somewhat coarse, but not of sufficient prominence to be observed in the print; and, finally, the rapid and forced one's result, as thoroughly rotten a specimen as could be, entailing plenty of work for the artist whose duty it was to finish its prints. Here is an argument for the employment of slower plates when rapidity is not a paramount necessity, and matter for the exercise of the brains for experimental plate makers in an endeavour to reduce the silver-bromide particle. Even supposing that the chemical or physical condition are such that to produce silver bromide in its most sensitive condition involves the large particle, are we sure there are no means whereby its greater fineness may not be secured by mechanical means? What effect would grinding the finished emulsion have? The query is worth an experimental answer, for it is by no means certain that breaking up the particles by mechanical methods would lower its rapidity or develop other evils. So much for want of definition and granularity.

Negatives for direct enlargement on paper or opal are best when of but moderate density, well exposed, and full of detail, but without a suspicion of fog. Fog is fatal to richness of shadows and to warmth of tone, even when negatives are strong and enlarged in a very powerful light; clouded shadows tend to give grey and muddy effects by shortening the scale of tones. For experimental proof, select two negatives as near as possible alike in strength and colour, except that one has a trace of fog, while the other has not. Make a similar enlargement from each, in either case doing the best possible to secure a good picture and to eliminate the effect of the fog. When fixed and dried, place them side by side and note the difference. There will be depth and richness as well as some sparkle in that from the immaculate negative to distinguish it from its fellow, which wears a more subdued appearance—good enough, perhaps, to pass muster by itself, but not in company, unless as a second rate. Allow me to digress for a moment. This plan of having a standard to judge by should be adopted by all beginners, and form part of the system of every enlarging room, where examples of work exhibiting all the most desirable qualities should be placed in a good light and handy for reference, and be, as it were, ever before the eyes of the operators² for no man can be quite sure of his judgment in all states of light and weather, and its aberrations from the influence of health. It may tend to produce feelings of dissatisfaction which, although uncomfortable, are, nevertheless, right and safe. These standards should only be entitled to their places of honour till better ones are produced. Years ago, in producing transparencies, proceeding thus was a great favourite of mine. As each was produced it was compared with its predecessor to oust it or not from the premier position, as the verdict was for or against its superiority. Keep this kind of thing going and

the standard soon becomes a very high one, which proves a good stimulant, if never reached, to raise the tone of the work and to refine the operator. To return. Hardness, great density, and fog are alike fatal, if not insuperable, obstacles to the production of the best direct work.

Negatives intended for enlargement should be employed for that purpose before they have been varnished or much printed from, for the dust and messes they pick up in these operations is a great distraction, and necessitates much labour on the enlargements where they appear to get more than their share of prominence. Retouching, especially of the description of hatching, is better kept off, as this kind when enlarged is very obtrusive, and adds much to the tedium and labour of working up the prints. If it be in the nature of a fine stipple it is not so objectionable, and may be left to take its chance, as it affords a by no means difficult ground for the artist to work upon. Negatives to be reduced are best retouched, they become still more refined in the operation. It must not, however, be overdone, or the smaller copies become insipid, and have too much of a French-polished look about them.

When the enlargements are to be made from enlarged negatives the minor defects of great density and fog are not of so much importance, it being quite possible to make a good enlarged negative from a small one not by any means of a good-looking type. In the early days of gelatine, over-exposed and dense negatives buried in fog were common enough, some requiring a week or more to get through them for the transparency, which, when obtained, other negatives could be made of usual density to print in twenty minutes or half-an-hour—a considerable difference if a dozen or so prints were wanted. If a mere ghost of an image in the way of a transparency, full of detail and pure in the lights, could be obtained from one of these “paving stones,” intensification would do the rest and give the power of reproducing a small negative of good quality for direct enlarging, or of making an enlarged negative for carbon or platinotype printing.

We have now arrived at the transparency. The earliest methods of producing these for enlarging purposes were by wet collodion, or by one or other of the dry collodion processes then in vogue, albumen coming into use somewhat later as a secret process. For enlarged transparencies, either for the method introduced by Sarony in 1872, for the purpose of producing the enlarged negatives used in connexion with Vanderweyde's style of finishing for enlarged paper negatives by Blanchard's method, or the production of large negatives in carbon tissue, wet collodion (bromo-iodised) and iron development stand alone. As these transparencies were required to be vigorous, and were often ultimately converted to decorative uses; it was a common practice to warm them up in tone by plunging them to fix in a dish of hyposulphite of soda only slightly washed from the iron. They were retouched and nicely got up before making the negatives from them, and should the latter be made by either of the contact methods their shadows were strengthened on the back, just as negatives are in the lights, giving a double chance of securing richness and vigour in the final result. Fixing the transparency half washed greatly improves the tone, provided the fixing agent be hypo. With cyanide of potassium a like advantage is gained by slightly over developing the transparency, thoroughly washing and fixing in a weak solution of this substance, and allowing it to remain on the plate for three or four minutes afterwards. This appears to dissolve out a slate-coloured element from the deposit, and to leave the transparency warmer and brighter, but slightly thinner, than it would have been if simply fixed and washed immediately. Amateurs who are adepts at lantern slide making by the wet process should note this. Weak cyanide or a weak solution of cyanide and iodine is a great power in skilful hands.

Collodion transparencies are at their best when thus made to full size for the negatives to be made by contact. They are not of the first class to enlarge from on account of their liability to halation and spreading of the light's action in the film as it were, producing when enlarged that peculiar inlaid and woolly look which at once proclaims the enlargement. Albumen transparencies were more refined in character, and not so liable to these defects; their deposit being finer, partook more of the nature of a stain than being composed of particles. The process was rather messy and somewhat uncertain. It was mongered at two guineas, a common fee for information many years ago. The carbon transparency had by this time borne down all opposition by its great superiority for the object in question. The knowledge of the conditions under which it could be successfully made was still in the hands of a few, and it was not till some years had elapsed before all the details were public property. It is, undoubtedly, the transparency of transparencies for enlarging, the points in its favour being not a few. It accurately reproduces all the qualities of the original negative with neither solarisation, halation,

nor other evils to which camera and contact transparencies in silver are subject; and being a contact product itself, made by diffused light, the defects on the outer surface or in the substance of the glass bearing the negative film are not imprinted. It is not so with contact negatives on gelatine plates, for being exposed to artificial light of greater directness, every bit, scratch, and bubble of the glass is impressed in all its details. Its freedom from solarisation and other defects peculiar to silver cannot be made too much of, as it is from these imperfections that the worst evils arise to point the argument against enlargements.

JOHN HARMER.

PHOTOGRAPHIC USES OF URANIUM.

THERE is at present no very extensive employment of the properties of the salts of uranium in photography, although in years past advantage has been taken of certain characteristics possessed by the uranic compounds to found various printing processes which are now practically obsolete. Chief of these was perhaps the well-known Wothlytype. In this, I believe, the uranium salt was dissolved with either silver nitrate or gold chloride in collodion, which was spread upon paper, dried, and exposed as usual. The progress of the picture could be watched, the “developer” being intimately united with the salt to be reduced; fixing and a thorough washing followed. Thus gold or silver, or, if toning were resorted to, both metals formed the completed image.

The chemical principle that governed this reaction was, of course, the familiar one that the uranic salt is reduced to the uranous state by the action of light, and that the gold or silver was deposited wherever such action had taken place. The same reaction holds good in another but simpler form of uranium printing, namely, where a solution of uranic nitrate is brushed upon paper, and this, after being dried in the dark, is exposed behind a negative. Upon development with either gold or silver we have a purple or cold grey picture, due to the deposition of Au or Ag respectively.

Mention of the negative-intensifier recommended I think by Eder, in which uranium nitrate is employed with potassium ferricyanide, possibly exhausts the list of uses to which the salt is or has been recently put; but as I am relying upon memory there may be, and probably are, other photographic formulae in which it plays a part. These, however, are doubtless of small importance, otherwise one might naturally expect to have heard of them. The method of intensification alluded to is frequently employed, and is said to be permanent in its results. Of the latter advantage I am not able to speak, but the capacity of the uranium intensifier for imparting a considerable increase of opacity to the negative is unquestionable. I do not propose further to consider this particular use of uranium in photography, for the reason that next to the admission of its simplicity and efficacy as an intensifying agent the simple fact of its having survived the innumerable changes of photographic procedure during the last eight or nine years seems to my mind to constitute a conclusive piece of evidence in its favour. The following remarks have reference only to the influence exercised by uranium conjoined to other agents over the appearance and constitution of positive impressions.

It is not, I consider, an unreasonable speculation that the second process of uranium printing above alluded to is one that is susceptible of great improvement. Two features of it always seemed to me to commend it to the attention of the experimentalist, namely, the simplicity of working and the rapidity with which the uranous image is formed. In these respects it will bear favourable comparison with several other printing methods now utilised. Those who have tried uranium printing, and published their experiences, invariably appear to have contented themselves with more or less satisfactory pictures in brown, purple, or grey, due respectively to development with potassium ferricyanide, gold chloride, and silver nitrate. In my belief these three tones, neither of which can be ranked as wholly pleasing, except as occasional alternatives, are capable of infinite modification, and certain experiences recently met with point to a confirmation of this view. I take the gold image as the general type of uranium positives. By “developing” with any of the toning baths used for albumen-silver prints, instead of the plain gold solution a variety of tones may be obtained. With acetate of sodium the colour of the picture is a brownish purple, with carbonate a brownish black, with borax brown or sepia, and so on. I find, almost as a rule, that the characteristics of the various toning solutions employed with albumen-silver prints are preserved with uranium pictures, and that one thereby possesses absolute control over the colour of the finished picture.

If perfectly plain paper, Rives or Saxe, be sensitised with the uranium solution the ultimate image will have a sunken appearance that is fatal to gradation of tone and vigour. The picture is, in fact, partly

lost. I have endeavoured to obviate this by selecting a heavy rough paper, such as that upon which architectural drawings are made, and giving it a preliminary sizing of arrowroot. The net result of my attempts convinces me that it is feasible by these or similar means to retain the uranous image practically on the surface of the support, and that the final picture may possess a greatly increased range of tone and plenty of strength. I was impressed with the fact that where a sizing preparation is resorted to there is a perceptible diminution of sensitiveness. While I should not venture to urge that uranium printing has in it the elements that might eventually secure its general adoption, I am of the view that a little research and experiment may not be without profit, and to that end shall further pursue the matter.

In a recent communication to a provincial society upon a cognate subject there is a description of a printing process, termed by the author, *mercuro-uranotype*, which I read with much interest, as it appeared about the time when I myself was engaged in a few attempts of the same nature. Adhering as closely as possible to the author's instructions I was unable to confirm Mr. Reynolds's experiments, save in a partial and unsatisfactory degree. I did succeed in getting a *mercuro-uranotype* impression, but only after lengthened exposure, and then the picture was relatively faint and weak. I observed that in the hands of Mr. Reynolds the picture attained "full strength" in a few minutes, but under no circumstances could I obtain a print as bold as with plain uranium nitrate. My failure was probably due to defective manipulation, and may be avoided upon a repeated trial.

Almost concurrently with the publication of Mr. Reynolds's (to me, at least) extremely interesting experiments was the appearance of a communication to a metropolitan society, embodying some experiences of the toning of silver bromide emulsion pictures with uranium nitrate and potassium ferricyanide, the constituents of Dr. Eder's negative intensifier already referred to. If one may presume to criticise Mr. Eder's remarks they struck me as being very lucid, and I was able without difficulty to arrive at satisfactory modifications of the tones of bromide prints by following his instructions. That gentleman recommends ten per cent. solutions of both salts. The picture after fixation is to be washed in acidulated water and then freed of the acid and treated with equal parts of the solutions named in twenty parts of water. After toning another washing and transference to a new hypo or alum bath. For the latter I do not recognise a necessity, and so in the few trials made omitted it, substituting for it, after a thorough wash and soak, an acid bath to remove any traces of insoluble compounds that may have remained on the print. A personal preference for less marked tones than the deeper browns given by employing the solutions at the strengths suggested led me to considerably weaken them. By this means I obtained what I aimed at, namely, an alteration of the cold black of the untuned print to a less determined hue, brown black, of greater range. I agree that a bromide print may be considerably improved in this latter manner by the application of the uranium-ferricyanide toning solution, which, moreover, possesses great latitude of power in imparting a well graduated series of pleasing tones.

Another useful application of the uranium-ferricyanide toning solution is in the modification of the colour of gelatino-bromide opal pictures. Here, as with paper positives, one may run up and down the gamut of the brown group of shades and tones with perfect success. I have so employed the formula detailed with satisfactory and pleasing results. For those who do not like blacks or cool greys this method of toning may be confidently recommended. It will, of course, not escape remark that with bromide paper and opals that are developed with oxalate of iron very stringent care is required to free the film from ferrous compounds before the application of the uranium-ferricyanide solution, otherwise ruinous blue stains are sure to appear. I attach little, if any, importance to the danger of yellow stains from the toning solution if its action be not protracted beyond a few minutes. In my trials some opals, with plenty of virginal margin, came out of the treatment quite immaculate, although only ordinary precautions were adopted to preserve their whiteness.

THOMAS BEDDING.

SOLARISATION AND POLARISATION.

THE position taken up at the commencement of this suggestive sketch, when a close connexion was assumed between radiant and electrical energy, requires not only that it be shown that more than a merely fanciful resemblance exists in the action of each as manifested in photography, but necessitates some reference to electrical polarisation. And here, at least, the writer is of opinion that a comprehensive grasp of the entire question and a careful examination into the causes of certain minor effects lead, and rationally lead, to the same conclusion.

Before proceeding to sum up, it were well, perhaps, to give some further examples of the mutual meddling of light with the affairs of electricity, and of electricity with what concerns light.

When a couple of holes are drilled through the poles of a powerful electro-magnet, and a polarising prism fitted at one hole, an analysing prism at the other, the analyser being turned so that all light is quenched, the interposition between the poles of a thick rectangular bar of silico-borate of lead (= "heavy glass") will produce no effect, but whenever a current is passed the plane of polarisation is rotated, and light is seen. When the current is passed in the opposite direction the rotation is opposite also. The amount of the rotation is directly as the strength of the current. All transparent solids and liquids exhibit a similar effect. Solutions, such as ferric chloride in alcohol, however, give a rotation in an opposite direction to that of the current. A powerful permanent magnet may be used in the same way. It is specially to be noted that each elementary ray of colour requires a different degree of rotation, which is inversely as the square of the wave-length. Faraday, the author of the *Induction Theory of Electricity*, who was the first discoverer of these phenomena, explained them in a manner more in harmony with the views previously indicated than with the opinions of those who hold that light consists of purely mechanical undulations.

Kerr's experiment is equally instructive. The poles of an electro-magnet being polished, a beam of polarised light is reflected from one of them to an analyser. When the current is passed so that the reflecting pole is positive, the plane of polarisation of the reflected beam is turned one way, when passed so that the pole is negative, the plane is turned in the opposite direction. Kerr also took a couple of plates of brass and placed them parallel at a short distance apart in a cell with parallel glass sides, and filled the space between with carbon disulphide. The plates were insulated from each other and connected with the two poles of an electric machine, and plane polarised light passed through in a direction parallel to the plates, the plane of polarisation of the light being inclined to them at an angle of 45°. The emergent light was examined with a Jamin's analyser, and on working the electric machine the bands moved across the field. It was found that the axes of the emergent elliptic vibrations were parallel and perpendicular to the plane of the plates, and that the difference of phase between the two components in these two directions was proportional to the square of the electric force at each point. Glazebrook, from whose chapter on electro-optics the foregoing examples are selected, states that by placing two small metallic spheres or a sphere and a pointed conductor in a dielectric medium, the same effects can be still more easily produced. When connexion is made between the conductors and an active source of electricity, and plane polarised light is passed through the liquid, it is seen to have become doubly refracting.

Of Becquerel's experiments on the production of electrical currents, by the unequal exposure to light of a couple of iodised plates of silver, &c., placed in a liquid conductor, there is not sufficient space to treat.

There are many other examples of the same kind which might, but which must not be cited. The action of light in diminishing the electrical resistance of crystalline selenium, and the acquisition of electrical polarity by the ends of a crystal of tourmaline on varying its temperature, whereby it has been shown that the polarity in the same end is reversed according as the crystal is heating or cooling, can only be mentioned in passing.

If light be allowed to fall unequally on a couple of similar metallic conductors immersed in an alkaline solution of a silver haloid, and the conductors be connected with a delicate astatic galvanometer, there will be a deflection of the needle in one direction or the other, according to the relative amount of the exposure, and according also to the colour of the light employed. By alternating comparative darkness with bright light, or even by alternating two complementary colours of light, a reversed current, indicated by an opposite deflection of the needle, will be manifested.

In so far as it is true to say that there is no substance which light cannot penetrate, it is equally fair to maintain that there is no such thing as a perfectly conducting or perfectly resisting body. Glass stops light and conducts electricity. Silver opposes resistance to electricity and transmits light, and it is a pertinent parenthetical question to ask how and in what manner it does so. Are the blue rays bent more or less than the red? Iodine, as we have seen, gives a reversed spectrum, in large bulk looks purple, and in small quantity yellow.

Faraday's induction theory is based on the idea that the medium through which induction takes place is not a passive patient, but an active and essential agent; and that induction is due to the polarisation of the particles or molecules of the medium separating the body acted upon from the body or force which acts.

Light-action in photography primarily implies reduction. Reduction in turn implies liberation of the halogen. There is this marked difference, however, between the reduction induced by the printing-out and the development of an image, namely, that in the former case the visible effects are the outcome of a single external and continuous cause, while in the latter case the visible effects are due to two causes, and depend upon the force brought to bear on an internal and inconstant condition accompanying the first. It is, at the outset at least, to the haloid salt itself that light applies its separating force.

While chemical combination frequently accompanies and assists reduction, the centres of the two actions are essentially separate—when the forces act simultaneously.

The conditions which favour the deposition of metal upon metal in one and the same film are not those which promote the union of metal and halogen.

Although it is generally acknowledged that both forms of combination are due to difference of potential, yet the first is usually classified as an electrical, the second as a chemical question. To get at the root of the matter it is absolutely necessary to have a fairly clear conception of the relative merits of Volta's hypothesis—recently very strongly supported by an experiment of Sir William Thompson—that electro-chemical action is due to the mere contact of heterogeneous metals, as opposed to the opinion of almost all the more recent writers on electricity, to the effect that current electrical action is the result of the chemical affinity existing between the more basyious of the galvanic pair and the chlorous element or radical of the conducting liquid. It is not contended here that light begets current rather than frictional electricity, save in so far as it is assumed that light is not a mere mechanical action. Either branch would equally serve to illustrate the parallels which suggest themselves.

To resume. It may be readily seen then that any inequality in the quantities or mass of the elements separated is equivalent to a modification of the direction of the strain of the effective forces, and in so far as the light-obstructing or impeding halogen is dissipated either by escaping from the seat of action, or by recombining elsewhere, the reduction at a given centre will be promoted, while in so far as it remains unaltered in the spot in which it was liberated, it must exert some influence by interposing its specific resistance to the normal action of light as an inducing agent.

Solarisation and halation are not identical, although they may have a common cause. It is quite possible that film photography may show that while lateral spreading may be aggravated by internal reflection it is not initiated by it.

For the present, however, we will leave halation alone, simply emphasising the fact that a mathematical consideration of the laws regulating induction, not only admit of, but insist on, a "round-the-corner" or lateral action of electricity.

In the same way as we would apply the laws regulating the passage of a current of electricity along a wire of unequal density let us now consider the action of a ray of light of a definite wave-length upon a rectilinear chain of molecules of silver bromide, of which one end only is directly submitted to the change-inducing force.

At the outset there will be a difference of potential implying a certain electro-motive force, and a current will be set up, the intensity of which will be equal to the quotient of the electro-motive force by the resistance.

After the lapse of a given time a certain amount of work will be done on both poles, or, as it may be expressed here, on the chain itself, according to the dimensions of the unit of potential.

If at this stage we were to interpose a delicate astatic galvanometer, we should observe a definite degree of deflection on the part of the needle in a given direction, and if in place of such an instrument we apply a developer (another test of electricity) we are able to estimate the intensity and direction of the current by the amount and direction of the metal deposited.

In order to realise the conditions which alter the difference of potential, and that we may form a fairly clear idea of the increments of acceleration and retardation, let us remember that the fundamental conception of electricity—a conception isolating it from every other science save magnetism—is that of attraction and repulsion, acting according to the law of inverse squares, that polarity, whether of mass or molecule, is essentially characteristic of electrical separation, that the induction theory assumes all bodies to be conductors, though not all conductors alike, and that polarisation has an effect as well as a cause.

As familiar examples of the last clause, the case of the reversed polarisation of the poles of a battery, or, in other words, the accumulation of opposite poles on their surfaces, and of the electrolyte whose polarisation they in turn determine, may both be cited. It only remains then to show in what manner this secondary current, referred

to a galvanometer, proof-plane and electrometer, or developer of ascertained resistance, can exceed the primary current in strength to be able to sum up all the factors of normal, neutral, and reversed photographic action.

The key to this is found in the distribution of electric density over a surface variable in size and shape, and of the tension—proportional to the square of the electric density—both of which must be largely determined by the rate of accumulation or diminution of the dielectric condenser or insulator, which in this case consists of the liberated halogen.

1. When the two circuits are quickly brought near each other, the galvanometer is seen to indicate an induced current, which flows along the induced wire in an opposite direction to that of the inducing current. As soon as the approaching movement stops, the needle returns to zero, and remains there as long as the two circuits maintain the same relative position. If now the two wires are withdrawn from each other, a new induced current is set up, but this time it takes an opposite course to the first-induced current.

2. Let us now leave the conducting wires in a fixed relative position, and let us change instead the intensity of the current. If this increases, it develops an induced current in the opposite direction to that of the one inducing it, precisely as if the distance between the wires had been lessened. If the inducing current remains constant, it produces no action; if it diminishes, it gives rise to a current opposite to that originally induced and similar to that caused by separating the wires.

These laws are general, and may be summed up thus:—"There is an inverse current in the induced circuit when the inducing current begins, increases, or approaches. There is a direct current produced by a contrary action, that is when the inducing current ends, diminishes, or recedes. The mean intensity of each induced current is augmented when the displacement or variation of intensity increase in extent and diminish in duration."

Now, since electric density and tension increase as the surface of the charged and insulated conductor is diminished, and since the tendency of the electricity to escape, or induce electricity of opposite sign is greatest at a point, it seems fair to argue that the simultaneous decrease in the effectiveness of the charging force, and the increase in the perfection of the insulation, will produce at one point of the conductor or another, first, a tension sufficient to admit of communication with adjacent particles (not absolutely in contact) and of the establishment, first of equipotential, and next of a secondary current stronger than the original one, of reversed sign, and tending by the consequent re-establishment of equipotential to establish a condition of polarisation, which the comparatively infinite power of the charging force of light would in time (t, t^2, t^3, t^4 , &c.) be able to cause an alternation of recurring phases of approximately normal and reversed currents, with neutral or equipotential stages between each extreme.

Some such course of reasoning is suggested by the repeated testing of the nature of the so-called "latent" image, by what we have here termed a liquid galvanometer, which we have formerly shown to owe its action to the specific inductive capacity of the electro-positive or accelerating ingredient present, the depositor being purely and simply a needle-producer.

HUGH BRENNER.

PLATINOTYPE PRINTING.

[A Communication to the North London Photographic Society.]

PLATINOTYPE, which may be considered to be the most artistic of photographic printing processes, may be separated into its three modifications—the hot bath and cold bath, in which a faintly visible image is developed, and the Pizzighelli printing-out paper. The hot bath process, again, may be divided into the black-and-white and the sepia papers. I intend to give you a rough outline of the preparation of the paper and working of these modifications, concluding by demonstrating the hot bath method, and handing round prints by it.

Platinotype may almost be styled an iron printing process, for while no trace of iron or its salts is found in the finished print, certain salts of iron are mixed with the platinum salt, which is platinum combined with two atoms of chlorine ($Pt Cl_2$) as a means for readily reducing it; this, however, cannot be effected without the presence of neutral oxalate of potash, hence the use of the oxalate bath. There is no platinum in the paper for the cold bath process, it being coated with ferric oxalate, mixed with a very small quantity of chloride of mercury—somewhere about one grain to an ounce of ferric oxalate solution. When dry it is ready for exposure, which is about three times less than with silver printing.

It is absolutely necessary to store all papers for platinum printing in an air-tight tin containing chloride of calcium, which must be dried by heating from time to time. For the cold bath, however, it is important to have moisture present during printing, or it may be after printing and before development. If the paper is left in a dampish room for fifteen minutes

it should be sufficient. Prints made by exposing damp paper, or damping dry paper just before development, must be developed within one hour if the maximum of vigour is desired; by delaying the development some hours, the prints in the meantime being stored in a drawer so that they may retain their moisture, an increase of half tone and warmth of colour will be obtained. If it should be necessary to delay development for a day or two, the prints must be dried before a fire soon after being removed from the frames, and then stored in a calcium tube until wanted for development.

While printing, the lemon colour of the paper receives a greyish-coloured image, which, although faint, can, with practice, be judged as easily as silver printing.

The developer consists of oxalate of potash and potassic chloro-platinite—about thirty grains of the platinum salt to half an ounce of oxalate forming about six ounces of solution; a great many variations, however, may be made in the proportions of platinum salt and oxalate, and different effects secured. Development is effected by sliding the print face downwards on to the developer, which must be rocked after the development of each print to avoid scum marks. To clear the prints they are washed in three or four baths of a weak solution of hydrochloric acid after leaving the developer, to remove all traces of the iron salts, and finally washed for a quarter of an hour in three changes of water: they are then finished, and may be dried between clean blotting paper.

Pizzighelli's process differs from the above in being one that prints fully out in the frame without development; the paper contains the platinum and iron salts as well as the developer, and so prints and develops at the same time. Although excellent prints can be produced with it, for general work the results of the paper, as at present made, will not compare with the hot and cold bath processes. It is, however, excellent for printing from very dense negatives, and occasional negatives that seem extremely suitable for it. The paper should be breathed on before printing, as if it is quite dry the printing will be very slow and irregular. The best conditions for the preparation of the paper have scarcely been decided upon yet, and it is not quite fair to judge the process. The prints are cleared in the acid baths and washed for about a quarter of an hour.

The sepia and black hot bath processes are much alike in the general treatment. There are, however, some special precautions to be observed with the sepia paper, the chief being to protect it from any but the faintest rays of light; the prints, unlike the blacks ones, may be affected by light when in the acid bath. A special solution must be added to the developer to keep the lights pure. Over exposure cannot be corrected by using a cooler bath, as is the case with the black prints, and the paper does not remain good so long.

The paper for the black prints by the hot bath process is washed with a mixture of potassic platinous chloride and ferric oxalate, the proportion being about sixty grains of the platinum salt to one ounce of the iron solution. It will not keep good longer than twenty minutes or so, and must be applied to the paper directly after mixing. The ferric oxalate in the paper is reduced by the action of light to ferrous oxalate, which forms the faint visible image; this, when the paper is floated on the oxalate of potash bath, is capable of reducing the platinum salt in contact with it into metallic platinum; but the ferric salt, which remains unaltered, has no action on the platinum salt, leaving these parts, which represent the high lights of the print, untouched. The ferric oxalate is removed by the acid baths which follow the development. A good temperature for development is 150° Fahr., and when using this so much detail should not be apparent as when printing for the cold bath process, in which all the detail desired should be very faintly visible. There are, however, many methods of exposing the paper and developing it, and no fixed rule can be made, but the development must in every case be suited to the exposure or the result will be a failure. For instance, the paper may be printed until all detail is visible, but a very much cooler development must be used, say 80° or 90°; on the other hand a slightly short exposure may be given, and a temperature of 180° to 200° used. 150° should be taken as the normal temperature, and kept to until some experience has been gained, as employing all temperatures will lead to confusion, and nothing will be learnt. Some negatives require a special treatment, and both printing and development must be altered, while for a very dense negative the paper may be left out in a dampish room for some time, it will then print with less contrast and more half tone. A thin negative is better printed by the cold bath process, but negatives should be good and brilliant for platinotype printing. Any one taking up platinotype and getting only weak prints would do well to look to his negatives instead of blaming the paper, as the high lights should be fairly dense, and the deep shadows nearly clear glass.

Time for complete development should always be allowed; with a hot bath fifteen seconds will be sufficient, but if a cooler development is used, or the prints are solarised in the shadows, more time should be allowed. When the deep shadows are solarised, or appear lighter than surrounding parts, a hot and prolonged development is required to obtain sufficient blackness, as they have a tendency to look like brown paper. I have found breathing on solarised shadows useful, as in the presence of slight moisture they begin to print out and become dark before development, getting black almost directly the print is floated on the oxalate. Three or four acid baths of about ten minutes each are used, and the prints are washed as before. The process throughout takes much less time than

silver printing, and can be kept on all the winter, when it is nearly impossible to print in silver. Prints can be developed in weak daylight or gaslight, and prolonged washing is dispensed with. N. P. Fox.

PHOTOGRAPHY AND THE LAW OF ERROR.*

In my experiments the twenty largest holes were all that were utilised, and in these the error is certainly small enough to be negligible.

I must here put in a word to ask photographers to conduct experiments of this description with as much accuracy as possible. There is a degree of refinement in photographic experiments which is often quite unnecessary; but, on the other hand, the phrase, "about so much," should never be used unless it can be shown that such an approximation is sufficient.

Let me explain how the experiments were conducted. A gelatine or other plate was placed in the sensitometer and exposed for a given time to the light from an equally illuminated surface. It was developed and placed in the apparatus for measuring the transparency of deposit as I have recently described. The number of the holes was then placed as the scale for the base of the curve, and the transparency of each set up as an ordinate; a curved line was drawn through the extremities of these ordinates.

In the formula $A' = A e^{-kx^2}$, x was the number of holes from the first hole in which the action of light was apparently nil. To find k , x was taken some way down the scale, and the value of A' (which in this case was transparency of deposit) was taken from the curve A ; the total transparency was also known. This gave k . Using this value of k , the transparency of deposit was calculated for each ordinate, and, as before stated, the resulting curve was found to agree with that plotted.

I cannot say exactly at the present time why the formula does apply to photographic plates, though the theory would seem to point to a connexion between the transparency and deposit in the way I have indicated. Professor Rücker and myself have both had a try at the adaptation, but have not yet finished our investigations. It is, however, none the less true that the formula holds good when a negative is developed, or when a platinum print is developed, allowing for the light reflected from the platinum as well as from the background of white paper, as the examples I give show. But it does not hold good in the case of a silver print, for reasons which, I trust, you will appreciate. When light acts on chloride of silver it blackens it, and after the first short impact of light, of course, the subsequent light has to struggle through the various intensities of blackness to reach the silver salt below, and this must necessarily modify the result. On the other hand, when a plate is exposed to light, the change in colour is so small, that practically the light has only to struggle through the silver salt in its pristine state. The same applies very nearly to a platinum print, in which the change in colour of the iron salt is small.

In the appended table are two examples of the theoretical and observed curves, one being a gelatine plate and the other a platinum print.†

$$A = 124$$

$$k = .0116.$$

In the formula—

$$A' = A e^{-kx^2}$$

$$A = 45$$

$$k = .0072.$$

CAPTAIN ABNEY, C.B., R.E., F.R.S.

* Concluded from page 316.

THE CAMERA IN SWITZERLAND AND ON THE ALPS.*

From Lauterbrunnen to Grindelwald there are numbers of excellent pictures to be obtained, so many that it would be difficult to particularise them.

At Grindelwald one is in the midst of the mountains, and in the season parties with guides are constantly starting on mountain expeditions. One of the earliest of this season's ascents of the Wetterhorn was made whilst we were there; the party, which left in the early morning, were to arrive at nine o'clock in the evening of our arrival at the hut half way up the Wetterhorn, sleep there the night, and start for the summit early in the morning. They took with them a signal rocket to be sent up at nine o'clock; all the guests of the Bear Hotel, eighty in number, turned out to see the signal; it was duly given and answered from the hotel by a flight of rockets, coloured fires, and fireworks. Amongst the groups gathered there the fatal accident last season on the Wetterhorn was naturally a subject of conversation; the fatal leap was, I think, across a crevasse, the foot slipped, and the young man missed his footing on the opposite bank, and, falling backwards down the dreadful abyss, was dashed to pieces; the guide sprang forward to seize him as he was falling, and actually touched his heel, but was unable to obtain a grasp; possibly two lives would have been sacrificed instead of one had he succeeded in doing so. The guide pathetically said he would have given his life to save his companion.

The Wetterhorn can be advantageously taken from the terrace of a hotel you will find on your left on the way to the Wetterhorn from the "Bear" (f-34, one second), also a little off the pathway on the way to the Gorge, but before reaching the stream.

On your way to the Wetterhorn the Superior Glacier will be taken and the ice cave in it, interior and exterior. The interior should be visited; it is not easy to describe the effect of the soft blue tint of the light admitted through the icy walls and vaulting of the cave and the brilliant white light from the outside reflected on to the sides of the cavern through the entrance. The light is very aquatic, though not so much so as it is on the snow and ice on the mountains. Cap off and on, f-34, I found sufficient at four in the afternoon; the outside of the cave with the face of the glacier was taken about the same time, and in much shorter time. The lower glacier is best taken on the way to the Gorge, half way down the hill from the "Bear" to the stream, at ten to eleven in the morning. You will observe from the photograph that the effect of the light at that hour is as good as could be.

The Gorge is well worth two plates, one from the bridge on the outside, one from the side of the rocky bed of the torrent, showing the wooden platform strutted out from the face of the rock, and taking in the bridge within the Gorge (f-34, three seconds).

Another day must be given to the Mer de Glace and the Schreckhorn Glacier; the latter requires some hours' climbing to reach, and by another route. For snow and ice I had provided myself with a stop which I made out of sheet zinc, requiring three times the exposure of f-34. With the use of this stop I succeeded in getting all my ice and snow pictures by cap off and on exposures, but the weather was dull; for clear weather and bright sunshine I should either have manufactured a smaller stop or given shorter exposures with f-16 or f-34. For instance, the Fiesch Glacier from Zossenburghorn was taken in rain, the guides crossing the glacier; Schreckhorn was taken in a rough storm.

Remember to have your boots spiked if you have to go for miles, as we had, over ice and snow, it may have many an awkward fall.

On leaving Grindelwald we sent a carriage on to meet us at Lauterbrunnen, and walked to that place over the Wengern Alp, some six thousand feet above the sea level. A more delightful walk could scarcely be imagined; the ascent from Grindelwald is gradual for an hour or two, through wood and open country; as the summit is approached the woods are left behind and the path leads through meadows covered in June with flowers of the most varied and brilliant tints, which grow in the wildest profusion—primulas, campanulas, soldanellas, ranunculi, great Alpine columbines, anemones, vetch, pansies, intensely blue gentians of several varieties, including the rarer marsh gentian with its deep blue flowers; here and there were thickets of crimson rhododendrons, known as the Alpine rose. A herd of mountain cattle were browsing, some near, some far away, each with its bell (some of large size) tied round its neck. Climbing by the hour together is tiring work, so, throwing ourselves down on the grass in the warm sunshine, we rested with half-closed eyes, refreshed by the scent of the growing flowers and listening to the soft hum of the bee and the tinkling of the cattle bells, which sounded like the chimes rung from innumerable church towers and borne over the valley from distant villages. These sensations, pleasant as they were, could not be indulged in long; more climbing had to be done before the summit could be reached; higher up the snow was still lying in the hollows, and, though an unwise thing to do, we refreshed ourselves by laying our hands in it and taking a mouthful occasionally.

On the summit is an inn which had only been opened for the season on the previous day; on our arrival we were invited by the hostess to sit down at a table in the front of the house, we did so, but soon found out that the sides and legs of the table had been recently painted red; a clergyman who was taking temporary duty at Meiringen, and was on his way to Murren, and had joined our party, was badly painted, but he congratulated himself on his thoughtfulness in having put on very old clothes for the expedition, and, as the painting appeared to give him very real pleasure on this account, he was not much to be pitied; but one of the gentlemen who had put on a new double-texture waterproof with which to shield himself from the wind found it ruined; he went to the hostess and asked for something to help him to remove the paint. "She had nothing," she said. "But surely there was spirit of wine?" "No." "But the painters were at work; had they no turpentine?" "Yes, they had, but they wanted it for their own use." This gentleman was much put out by what he considered to be heartless and cold-blooded apathy, and swift retribution followed. Finding her near a door-jamb which he previously ascertained had been recently painted, he entered into conversation, and advancing gradually inch by inch she as gradually retreated until her back rested against the door-jamb. "Is the door-jamb freshly painted? If so, Monsieur feared Madame would be in the same predicament as himself. Would Madame turn round? Yes, it is dreadful! Unless Madame can remove it at once with the aid of some solvent the dress will be ruined." Madame retreated hastily, and her voice was heard calling loudly for man and maid, and the result was that a bottle of spirits of wine was produced, with which the traveller, chinking over the success of his ruse, saved his waterproof from utter ruin.

The descent on the Lauterbrunnen side brought us through magnificent mountain scenery. On the way up and from the top we had fine views of the Finster Aarhorn,

Monck, Schreckhorn, Eiger, and, in the distance, the Wetterhorn, all of them from thirteen to fourteen thousand feet high; here and there were revealed stretches of the enormous glacier, which is said to cover one hundred and twenty square miles and to extend from Grindelwald to Brieg, in the Vallais. The inn which we left was directly in front of the Jungfrau, though separated from it by a deep and vast ravine; owing to the clearness of the air, the Jungfrau seemed close at hand, and now and again the avalanches of ice and snow detached themselves from the masses high up the mountain and, moving slowly down the sides, visible by what appeared to be a puff of white smoke, but what really was a mass of snow and ice dashed into a million fragments, plunged headlong over a precipice some thousands of feet high into the abyss below, in volume sufficient to overwhelm a town, and with the sound of a roll of thunder which echoed and re-echoed from mountain to mountain. Further on Murren became visible; it was apparently within half an hour's walk, but we did not see the deep valley of the Lauterbrunnen nor understand that a descent of some thousands of feet and a similar ascent on the other side—which would occupy hours of hard walking—would have to be accomplished before deceptive Murren could be reached. Further down we left the barren and rugged rocks and reached the pine woods again; from thence a line of pack-horses and mules were emerging, laden, probably, with goods and supplies of food for the inn we had left; they made a good subject for the camera.

I have not dwelt on the views suitable for the camera on the Wengern Alp, they abound on all sides. Before leaving the subject of photography at Grindelwald I may say that M. Boss undertook to fit up at the "Bear" a dark room for the use of amateurs; this has doubtless been done.

The descent into the Lauterbrunnen Valley is most trying; the strain on muscles which are rarely exercised by going downhill by the hour together is worse than the fatigue of climbing. In due time we arrived at Lauterbrunnen; our carriage, which we had sent round by road, curiously enough reached the inn there at the same moment as ourselves.

If the return is made by Lansanne or Geneva, Fribourg can be taken on the way. The view from the suspension bridge (f-34, one second) should not be forgotten. There are bits to be had almost anywhere, whether you turn to the right hand or to the left after crossing the bridge.

I must confess that it was not photography so much as the organ at Fribourg—said to be one of the finest in Europe—which attracted me to the place. Recitals are given upon it daily. I have long since come to the conclusion that these Continental organs, of which so much is said, are greatly over-rated; they trade on their ancient reputations. I have heard no organ on the Continent which will compare for a moment with that in Salisbury Cathedral, or the Albert Hall, or with any of our first-rate modern organs. The Fribourg organ possesses stops of much sweetness, as, for instance, a flute and soft reed, though the latter was probably of modern construction, for I imagine no reed made two hundred years ago would be of much value now. The diapasons were full, round, and mellow in tone, of the quality one would expect from pipes of large scale blown on a low pressure of wind, but otherwise there was not much that was remarkable in the organ; and the full organ was not well balanced, the bass quite overpowered the treble. To the persons who frequent these recitals the cor humana appeared to be the attraction. Our best organ builders will not encourage the use of any clap-net stops of that description; the best cor humana is a well-taught choir; and where a good organ is to be found it is generally easy to get that most perfect of cor humanas in the natural form, and few musicians would care to listen to a vile imitation after hearing the original. The recital ended, as these recitals generally do, by an illustration of a storm in the mountains, which opened with an imitation of an Alpine horn, then came the storm with free use of a thunder stop, then the prayer of the peasants, on the cor humana stop of course, then things settled down again. The performance is much regarded by the audience generally. One wonders some enterprising individual does not get up a new sensation in, say, an illustration of "A day in the country." It might commence on a "cock" stop, which, like the Alpine horn stop, would announce the break of day; the precious cor humana might be brought in in illustrating an altercation between the farmer and his men; a "cow stop" and a "pig stop" might be effectively introduced in the course of the piece; and the whole might conclude on the "donkey stop," which, by successive and combined hee-haws, and finally by a chorus of hee-haws simultaneously in different keys, would bring the whole to a fitting conclusion and "bring down the house."

The Cathedral porch possesses a peculiar piece of sculpture over the door which is worth photographing, and you would scarcely leave Fribourg without photographing the Hotel de Ville and the lime-tree of historical interest. The story connected with it is too well known to be repeated at length; the story, I mean, of the young man who ran from the battle-field of Morat to announce to his fellow-townsmen the defeat of the Duke of Burgundy. He reached the market-place, declared the victory, and instantly fell dead from fatigue and over-excitement; a branch of lime-tree which he bore was planted on the spot upon which he fell, and this tree, with its aged limbs supported on all sides by props, is the original slip of lime-tree planted four hundred years ago, at least so it is affirmed.

From Fribourg Lansanne is easily reached. Lansanne is very central for all places of interest on the Lake of Geneva. The cable railway to Onchy is a great convenience; it takes the visitor from Lansanne to the lake-side in five minutes, from whence the steamboats, which are constantly calling, will take him down to Geneva or to any intermediate port, or up to Villeneuve, Chillon, Clarens, Montreux, or Vevey.

The favourite view of Chillon, with the castle jutting out into the lake, which is here three hundred feet deep, with Villeneuve in the distance, and the Dent du Midi towering above it, snow and possibly cloud-capped, always makes a picture, and the usual f-34, one second if fine, two seconds if cloudy, may be safely given. A picturesque view can also be taken from the land a little to the left of the entrance; if a short-focus lens is used the road and railway can be avoided and the little vineyard below it will give a suitable foreground.

The inner court, with its flight of steps on each side and irregular roofs, is worth a plate. The dungeon will, of course, be photographed; the light is said to be best for this purpose at five o'clock, but mine turned out well at a quarter past one with a quarter of an hour's exposure, f-11, though double the exposure would not have been too much. The military chapel adjoining it will require a slightly shorter exposure. There are many interesting rooms in the castle, which should be taken if a complete series is required—as the Hall of Justice (f-16, twenty seconds), the ancient kitchen, and the bedroom of the Duchess of Savoy. (For the last-named a very short-focus lens will be required.)

* Concluded from page 303.

At Montreux the gorge should not be forgotten.

There had been a question at Interlaken whether the camera should be taken to Lucerne and the Rigi or up the Rhone Valley, then to Zermatt, Chamonix, and Mont Blanc; the latter route gained the day, but some people coming down from the Rhone Valley to the Gishon Hotel, Lausanne, where we were staying, discouraged us by saying they had not had one fine day in three weeks. We should have persisted, however, had not cold and broken weather set in at Lausanne also. We waited for a change for three days, but as the fine weather appeared to have taken its departure for an indefinite period we reluctantly returned home, leaving Lucerne, the Rhone Valley, Zermatt, and Mont Blanc to be photographed on a future occasion.

PATENT COMPLETED.

IMPROVEMENTS IN LENSES.

No. 5194. DR. HEINRICH LUDWIG HUGO SCHRÖDER, 17, Althorp-road, Upper Tooting, Surrey, and JOHN STUART, The Hollies, Clapham, Surrey.—*April 7, 1888.*

THIS invention has for its object to provide a lens in which the errors of curvature of the image and colour correction incident to other lenses are overcome, and this over a large field of view. Lenses made according to this invention give a sharply defined image throughout the field, which is of great advantage in most or all applications of lenses, and especially so for photographic and other like purposes.

Hitherto all achromatic lenses (having either flat or other contact surfaces) that give a positive image have the convex radius shorter than the concave radius.

Now the distinctive feature of the lens according to this invention is that by employing glasses combined as hereinafter described, the radius of the convex surface is enabled to be longer than that of the concave surface, and at the same time a positive image is still obtained. The convex and concave surfaces may thus be arranged to represent parts of two concentric spheres.

According to this invention the objective is composed of a convexo-plano lens made of glass of a high refractive power and relatively low dispersive power, combined with a plano-concavo lens made of a glass of lower refractive power than that of the glass of the convexo-plano lens, but of the same or higher dispersive power than that of the glass of the said convexo-plano lens. The inner or contact surfaces of these two lenses are placed together, and preferably cemented, the convexo-plano lens forming the front portion of the objective.

By proper choice of the radii of the spherical surfaces of the lenses and of the glasses used, and of their thicknesses, an aplanatic lens can be made having a positive focus, that is, a lens giving a real image of an object receivable on a screen, and having great flatness of field and suitable colour correction throughout a considerable angular distance from the axis. The ratio of the radii of the two concentric spherical surfaces will depend upon the refractive powers and dispersive powers of the glasses used, as hereinafter more fully explained.

And, in order that our said invention may be fully understood, we shall now proceed more particularly to describe the same, and for that purpose shall refer to the several figures on the annexed sheet of drawings, the same letters of reference indicating corresponding parts in both the figures.

Figure 1 of the accompanying drawings is a transverse section of an objective made according to this invention, *a* being the convexo-plano lens of high refractive and low dispersive power, and *b* being the plano-concavo lens of lower refractive power and the same or higher dispersive power. The convex and concave external surfaces (marked respectively *e* and *d*) are portions of concentric, or approximately concentric, spheres having their centre at *f*, and the plane internal surfaces are preferably cemented together at *c*.

In order to obtain a plane image throughout a large field of view, the radii of the external surfaces (*e* and *d*) should have a certain ratio to each other dependent on the refractive and dispersive powers of the glasses used.

In practice it is found that the limits of the refractive powers of glass available for the front lenses of the improved objective are from about 1.59 to 1.61, the index being taken to be corresponding to the D line of the spectrum. Similarly the range of refractive powers for the glasses available for the back

Fig. 1.

Fig. 2.

lens of the said objective ranges from about 1.50 to 1.53, the refractive index being as before that for the D line of the spectrum. It is to be understood that these figures are given as being what are considered the best with glass as now generally obtainable.

With the before-named glasses the ratio of the refractive and dispersive powers which would produce the best radii, so far as flatness of field and suitable colour correction of the image are concerned, is given by the following tables:—

TABLE No. 1.

Dispersive Ratio = $\frac{w}{v}$	Dn = Index of Refraction relating to the Convexo-plano Lens.			DN = Index of Refraction relating to the Plano-concave Lens.
	1.59	1.60	1.61	
0.916	0.904	0.891		1.53
0.903	0.890	0.877		1.52
0.889	0.876	0.864		1.51
0.875	0.863	0.851		1.50

TABLE No. 2.

Ratio of the Concentric Curves = f

Dn = 1.59.		
DN	$\frac{w}{v}$	f
1.53	0.916	1.072
1.52	0.903	1.086
1.51	0.889	1.100
1.50	0.875	1.115
Dn = 1.60.		
DN	$\frac{w}{v}$	f
1.53	0.904	1.083
1.52	0.890	1.097
1.51	0.876	1.112
1.50	0.863	1.126
Dn = 1.61.		
DN	$\frac{w}{v}$	f
1.53	0.891	1.094
1.52	0.877	1.109
1.51	0.864	1.123
1.50	0.851	1.138

Thus, for example, if the front or convexo-plano lens *a* have a refractive power of 1.61 for the line D in the spectrum and the back or plano-concavo lens *b* have a refractive power for the same line of 1.50, the ratio of the curves of the two spherical surfaces of the lenses (*e* and *d*) should be 1.138, in order that throughout the field of view the image may be plane with suitable colour correction.

Slight deviations may be made from the directions given above, as for example by slightly departing from the plane internal surfaces (*c*), or from the concentricity of the external spherical surfaces (*e* and *d*), or from the ratio of the radii or dispersive and refractive powers of the two glasses (*a* and *b*) given by the above tables without departing from this invention, but we believe that by following the rules given above the best results will be obtained with glass at present obtainable.

With the aid of these tables the requisite ratios of the dispersive power appertaining to the refractive powers of the glasses used and also the requisite ratios of the radii of the lenses may be calculated by the ordinary method of interpolation. The objectives may be used singly, as in figure 1, or combined, as in figure 2 (*g* being the diaphragm between them).

Having now particularly described and ascertained the nature of our said invention, and in what manner the same is to be performed, we declare that what we claim is:—1. The combination of a convexo-plano lens made of glass of high refractive power and relatively low dispersive power, with a plano-concavo lens made of glass of lower refractive power and the same or higher dispersive power (the said lenses having plane or slightly curved contact surfaces and outer concentric or approximately concentric surfaces), to form an aplanatic lens or objective giving a positive image, substantially as hereinbefore described with reference to the accompanying drawings. 2. The improved lens or objective hereinbefore described.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
May 20	North Middlesex Club	The Iron Room, Stroud Green.
" 21	North London	Myddelton Hall, Upper-st., Islington.
" 21	Bolton Club	The Studio, Chancery-lane, Bolton.
" 22	Photographic Club	Anderson's Hotel, Fleet-street, E.C.
" 23	Barton-on-Trent	The Institute, Union-street.
" 23	London and Provincial	Masons Hall Tavern, Basinghall-st.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

MAY 14.—Mr. James Glaisher, F.R.S., President, in the chair.

Mr. A. F. Hare and Mr. K. Ogawa, both of Japan, were elected members of the Society.

The PRESIDENT asked Captain Abney if he had seen a communication from Colonel Waterhouse, on orthochromatic photography, read at the previous meeting of the Society.

Captain W. de W. ANNEY replied that he had read it and seen the nice photographs accompanying it; he thought that the long time of exposure did not promise well for the anthracine blue. The alizarine blue he had tried himself, but was not prepared to stand up for it particularly. Colonel Waterhouse had stated that in one part of a photograph he had touched the line Z, and that was almost the beginning of the invisible part of the spectrum; so he did not think the process of much advantage for the photographing of the spectrum; for orthochromatic pictorial work it might do pretty well, but perhaps not better than cyanine. He thought Colonel Waterhouse's photographs to be beautifully sharp and clean; he did not know whose plates were used.

Mr. JOHN SPILLER remarked that they were Wratten & Wainwright's.

Captain ANNEY continued that photography would show certain lines of the spectrum double which could not be seen to be double by the eye, and that Professor Rowlands had admitted the fact.

Mr. JOHN SPILLER exhibited a specimen of rho-lamine, a deep red-purple dye, and said that Colonel Waterhouse had asked whether it belonged to the eosine group. He (the speaker) would hesitate to give an authoritative opinion, and after stating how it was made, he added that although it was a somewhat similar substance still he did not think it to be an eosine—in fact it was a basic colouring matter; no doubt Mr. Chapman Jones could better answer the question.

Mr. CHAPMAN JONES stated that he had no opinion to express.

Captain ANNEY said that it was dangerous to discuss patents before the Society.

Mr. T. R. DALLMEYER then read a paper upon *The Forms and Applications of Landscape Lenses*, which paper will appear in these pages in due course. In it he gave instructions to enable photographers to test their own lenses. He said that those who send out the Jena new glass tell absolutely what are the optical properties of each specimen forwarded, and on testing the glass himself he found the information furnished by them to be accurate; and some samples are marked in their catalogue as uncertain in their lasting properties. Landscape lenses including but a small angle gave the most pleasing pictures.

Mr. WILLIAM ENGLAND had always been a great advocate of single lenses; he used them whenever he could in preference to other lenses; he employed them for copying paintings and photographing statuary, as well as for landscape and other work in which it was not necessary to get straight lines near the edges of the plate. In many cases he found them to be better than portrait lenses for portrait work.

Mr. CHAPMAN JONES remarked that Mr. Dallmeyer had recommended a thermometer bulb illuminated by a lamp flame in the testing of lenses; he (the speaker) had tried that plan but preferred a candle in a spring socket, so that the flame should always be at the same level, and in front of the flame he placed a screen pierced by a small hole. The old fashioned single lenses were of much larger diameter than those of modern make, and had the advantage that the mount did not cut off the edges of the image. Was the tendency to make lenses smaller due to the demand for increased portability?

Mr. LEON WARRNEKE said that single lenses were usually not sufficiently rapid for studio use, but a friend of his in St. Petersburg had obviated this by turning the whole lens round, and had then obtained good portraits. What did Mr. Dallmeyer think of the plan?

Mr. GEORGE DAVISON thought it to be well to have the power of introducing at will a certain amount of diffusion of focus, and Mr. Lyonel Clark, by using, with a diaphragm of $f/4$, a large single lens of about six inches diameter, he thought, had produced some exceedingly pleasing large heads, better, he thought, than were obtainable with an ordinary portrait combination.

Mr. T. SEBASTIAN DAVIS thought that artists preferred to paint views which did not include a greater angle than sixty degrees.

Mr. FRIESE GREENE had found that portraits taken by the electric light were more out of focus with the same apparatus than portraits taken by daylight. Could Mr. Dallmeyer explain the matter?

Mr. W. E. DEBENHAM questioned whether Mr. Dallmeyer had demonstrated the advantages of spherical aberration, as he claimed to have done.

Mr. DALLMEYER agreed with Mr. Chapman that each lens should be of such dimensions as to give the best results; they were made smaller at the expense of equality of illumination. He had not seen the lens mentioned by Mr. Warnerke, he did not know what its correction for spherical aberration might be, so could not give an explanation.

Mr. DEBENHAM said that with the lens employed as stated, only the central pencils could be used.

Mr. DALLMEYER continued that Mr. Clark's lens would include so few degrees that, although he might get nice heads, he could not get good full-length figures. In answer to Mr. Friese Greene he did not know that there was any difference between solar light and the electric light to produce such an effect as had been stated; the electric light was simply a little richer in ultra-violet rays than solar light.

The PRESIDENT announced that the *conversazione* of the Society will be held on September 28 next, and that the exhibition will open on September 30.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

MAY 9.—Mr. C. H. Cooke in the chair.

Mr. G. W. ATKINS exhibited an 8 x 5 Ross' rapid symmetrical lens mounted inside the camera in such a way that the stops could be changed at will from the outside at any moment; he explained the nature of the mechanism by which this was done. One long diaphragm was used with apertures in it of different diameters. With the lens inside the camera, he said, there is no danger of light getting in through the diaphragm slot.

Mr. T. KERR exhibited a new quarter-plate detective camera which, with three backs unchanged with plates, weighed four and three-quarter pounds.

Mr. A. HADDON believed that there was one fault common to all the present detective cameras, namely, that they had no screen to partially protect the finder from extraneous light; he thought that some little opera-hat arrangement might be made for the purpose which would shut down flat on the camera when not in use.

The CHAIRMAN had never felt anything of the kind to be necessary with a detective camera.

The HON. SECRETARY asked if any member present had taken up hydroquinone as a developer and afterwards stuck to it.

Mr. J. J. BRIGINSHAW replied that he had done so.

Mr. H. D. ATKINSON had been steadily using it for the last five months.

Mr. POLLARD GRAHAM said that the effect of developing successively a number of plates in the hydroquinone developer was that the liquid took up more and more bromide until the last plate inserted behaved as if under exposure.

A question in the box asked who was the first to use coloured screens in connexion with photography.

Mr. W. H. HARRISON believed Mr. William Crookes to have been about the first; at all events, about thirty years ago Mr. Crookes interposed a solution of sulphate of quinine to obtain more true colour rendering. Although sulphate of quinine is colourless it cuts off some of the more refrangible rays which act on bromide of silver.

Mr. T. E. FRESHWATER could not get such sharp results on bromide paper as upon ordinary albumenised paper.

The HON. SECRETARY said that he should either roll the bromide paper well before printing or buy a bromide paper with a more highly glazed surface.

Mr. KERR remarked that printing with nearly parallel rays at the bottom of a box would give more sharpness.

Mr. P. EVERETT called attention to a statement in a journal that acetate of soda could be used in developers in place of a carbonate or a fixed alkali.

Mr. HADDON did not believe it.

NORTH LONDON PHOTOGRAPHIC SOCIETY.

MAY 7.—Mr. J. Traill Taylor (President) in the chair.

Messrs. C. M. Riches and B. Foulkes Winks were elected members of the Society.

The Hon. Secretary showed negatives on the Beernaert plates.

Mr. E. Clifton showed a photograph of the Eiffel Tower taken with a hand camera.

Rev. E. Healy showed a 10 x 8 negative taken with an eleven-inch focus lens. Mr. W. T. Coventon showed a stereoscopic camera constructed to rotate round any centre desired.

The PRESIDENT stated that this method was devised by Mr. Latimer Clarke in 1854.

Mr. H. M. SMITH then gave a demonstration on *The Carbon Process*.

The CHAIRMAN stated that whatever might be said of the want of permanence of other processes, the carbon print is absolutely permanent. The pigment in which the image is embedded finally becomes vellum, and any coloured pigment may be employed.

A unanimous vote of thanks was passed to Mr. Smith for his demonstration. Mr. F. W. Hart passed round prints of a light blue ornament on a cream ground, to show the advantages of using Edwards's isochromatic plates; they were taken with his flash lamp.

Mr. F. W. Few showed some plates covered with spots in the film, also some plates fogged by a minute hole in the flexible band in an instantaneous shutter.

The next meeting will be on Tuesday, May 21.

HOLBORN CAMERA CLUB.

MAY 3.—Mr. RICE (President) in the chair.

Mr. E. J. WALL delivered a lecture on *Isochromatic Plates*. He sketched out a short history of what had been attempted and the failures that had been made before isochromatic plates were produced, and then explained that this kind of plate was peculiarly sensitive to yellow, and handed round diagrams showing the colours of the spectrum and the colours in the spectrum most

favourable to be photographed with these isochromatic plates, which colours were yellow, green, orange, and blue; whereas in a photograph where an ordinary plate was used blue would come out nearly white, and light and dark yellow would be difficult to detect; on the other hand, with an isochromatic plate, light blue came out easily distinguishable from white, and the various shades of yellow were also clearly defined in their various shades. In a portrait of a sister having sandy hair taken on an ordinary plate the ruddy yellow of the features and hair comes out nearly black, but with an isochromatic plate the face and hair came out just like that of a fair person. Another illustration which showed the usefulness of these plates was an oleograph of a seascape just before sunset. There were three photographs of this—one with an ordinary plate from which it was very hard to discover the difference between yellow and black of the print; the second taken with an isochromatic plate, which gave a very much better result; and the third with an isochromatic plate, there being at the time of exposure a screen of pale yellow glass before the lens; this latter gave a very successful and artistic picture. As regards screens, Mr. Wall explained that they should be made of optically worked glass. They were nearly indispensable when photographing a blue distance and in getting good clouds that were of different shades of blue. He also stated that one of those screens enabled him to get objects clearer when there was a sort of yellow mist in the atmosphere, when such a state of things would be very detrimental to a photographer using an ordinary plate. Mr. Wall recommended long exposures, and showed a photograph of a snow scene—snow-covered road, and houses, and trees—taken without the screen, which was very good. He exposed it, with an aperture of $f/20$, about ten seconds on a medium isochromatic plate. In summer it would require about half a second with the same stop. The screen increases the exposure about three times, according to the various depths of tint; some increase the exposure to about ten times. The screen is to deepen the effect of the yellow and bring out some of the blue. These plates can be developed with almost any developer. He uses pyro, and glycerine, and ammonia himself. Must only be exposed to a ruby light, the darker the better. The plates will keep just as well as other plates. The quicker the plate the greater the sensitiveness to white light and to blue. Recommends the slow plates (if possible) if one wants to get the isochromatic effects. Hydroquinone acted very well on these plates, pyro comes next, and ferrous oxalate last. Isochromatic plates would give excellent results for cloud work.

MAY 10.—A general discussion took place, after which Mr. Fred Brocas developed an opal plate with hydroquinone.

The following were elected members of the Club:—Messrs. W. Ivanhoe Thomas, Thomas Whiting, S. Tingfau Chang, and G. W. Carter.

Mr. F. W. Thomas will give a lecture and demonstration on Friday next in the Club Room, at eight p.m., on *Platinotype*. On the 18th instant the Club will visit Waltham Cross.

SHAFTESBURY PHOTOGRAPHIC SOCIAL.

MAY 10.—Mr. D. Rintoul in the chair.

Mr. TOLLETT read a paper on *Working of Bromide Papers for Contact Printing*. He then exposed two pieces of Ilford bromide paper for forty-five seconds at a distance of one foot from an ordinary Bunsen's burner, then developing it in the maker's formula of ferrous oxalate solution. Result good. He next exposed two of Eastman's to the same light for thirty seconds and developed in the same solution as last, with excellent results. Fry's bromide paper was then exposed, one piece thick and the other thin, both making fair results, exposing for fifteen seconds at a distance of twenty-four inches, developed in hydroquinone developer.

There being no time for a discussion, it was adjourned till next Friday evening at half-past eight, when Mr. Tollett, if possible, will bring more specimens of these papers.

The SECRETARY announced the coming outing to Chingford on the 18th instant. Outside Liverpool-street Station, under the clock, at ten minutes to three. Amateurs invited.

NORTH SURREY PHOTOGRAPHIC SOCIETY.

THE meeting of this Society on the 30th ultimo was devoted to an exhibition of lantern slides, and about two hundred slides, the work of the members, were passed through the lantern. The majority of the pictures were of good quality and elicited numerous questions as to method of production, &c. A curiosity in the shape of a cloud picture including the sun perfectly distinct was particularly interesting, and there were some good examples of hand camera work.

THE Society also met on the 7th instant, when Mr. W. THOMAS read a paper on *The Coast of Yorkshire*. This paper, which was illustrated by lantern slides, was interesting, and Mr. Thomas, thoroughly master of his subject, was able to give practical information valuable to intending visitors to this district.

The next meeting, on the 21st, will be a special general meeting for the consideration of the proposed alterations of the rules of the Society.

BIRKENHEAD PHOTOGRAPHIC ASSOCIATION.

MAY 9.—The President (Mr. Paul Lange) in the chair.

Messrs. A. Grillon, Morris, C. Wall, and H. Bebbington were elected as members.

THE PRESIDENT gave an account of the first outdoor excursion to Chester, which took place on Saturday, the 4th instant, twenty-eight members turning out. Through the kindness of Mr. J. Collinge, his steam launch and barge were placed at the disposal of the party, which conveyed them up and down the River Dee. After lunch the party traversed to Eaton Hall, the seat of the Duke of Westminster, where permission to photograph had been granted, the total number of exposures for the day being two hundred and nine.

Mr. Archer exhibited a German hand camera which seemed very ingenious in its construction.

The PRESIDENT then gave a practical demonstration on *Developing Platinum*

Prints with the Hot and Cold Bath Processes. On proceeding to develop, Mr. Lange passed several prints round: No. 1, which he explained was under printed; No. 2, correctly printed; and No. 3, over printed. No. 1, being under printed, was then developed in a bath about 130°, No. 2 was developed in the same bath cooled down to about 100°, and No. 3 when the bath had cooled down to about 90°. On examination of the prints after clearing, &c., Nos. 1 and 2 were excellent in tone, &c., but No. 3 rather dark and hazy. Mr. Lange, replying to a question, stated that a much better result of No. 3 could have been got with a cooler bath. The second lot of prints from the same negative, and printed as above, Nos. 1, 2, and 3, were then developed with the cold bath process, Nos. 1 and 2 coming out very good, but No. 3 only fair, the tone being a very dark brown.

After an interesting discussion on the tones, manipulation of the bath, &c., the majority of members seemed greatly in favour of the hot bath process, the opinion shared by Mr. Lange as well.

A lantern exhibition of slides by the members terminated the proceedings.

LEWES PHOTOGRAPHIC SOCIETY.

MAY 7.—The President in the chair.

The HON. SECRETARY called the attention of members to the list of rules and classes for the exhibition to be held in October next, in which several classes will be open to photographers resident in Sussex.

The PRESIDENT read a paper on *Enlarging*. A bromide print was exposed during the reading of the paper and afterwards developed with a solution of hydroquinone. A collection of enlargements were exhibited by the President.

Mr. Corder promised a demonstration of *The Platinotype Process* for the next meeting, to be held on June 4.

DARLINGTON PHOTOGRAPHIC SOCIETY.

MAY 13.—Mr. G. Newby Watson presided.

A discussion on *Photographic Resorts* was opened by the Secretary, Mr. W. GARRITTE-BREWIS, in which several members took part. A large number of photographs illustrating the places visited were shown, and lent much interest to the meeting.

The judging of the prints sent in for the monthly competition was then proceeded with. Those sent in by Mr. E. B. Mounsey were found to be the best.

The next meeting will be held on June 17, when the subject of *Instantaneous Shutters and Shutter Work* will be brought forward.

DUNDEE AND EAST OF SCOTLAND PHOTOGRAPHIC ASSOCIATION.

MAY 2.—Several excellent specimen prints from Mr. Valentine Blanchard, by his platinum toning process, were exhibited, as also several by the SECRETARY, who stated that he had found the working of the process simple, and had no difficulty in getting tones quite equal to those of Mr. Blanchard's examples.

In concluding a discussion on *Hydroquinone*, Mr. JOHN ROBERTSON said that he had used it in his studio exclusively for five or six years, but had been obliged to abandon its use owing to the effect it had on his hands, similar to that of bichromate poisoning. On recovering he had tried the developer again, to prove if it were at fault; in a few days the old symptoms returned—first intense itch in the back of the hands, followed by the skin cracking and ulcers. The most efficacious cure was an old-fashioned one of a sugar and soap poultice.

The following were elected office-bearers for the ensuing session:—*President*: Dr. J. K. Tulloch.—*Vice-Presidents*: Messrs. John Matthewson and J. D. Cox.—*Council*: Messrs. W. Baxter, J. C. Cox, W. F. Hill, D. Ireland, G. G. McLaren, L. Ower, J. Robertson, W. Salmond, A. Stewart, and W. D. Valentine.—*Secretary and Treasurer*: Mr. V. C. Baird, Broughty Ferry.

Correspondence.

✉ Correspondents should never write on both sides of the paper.

ELECTRIC VERSUS DAYLIGHT FOR ENLARGING.

To the Editor.

SIR,—Will you kindly allow me to correct a slight error which appears in your last issue? In the report of the discussion following the paper of Dr. Harrison Low and Mr. Hodges, at the meeting of the West London Photographic Society, I am reported to have said that the Eastman Dry Plate and Film Company, after going "to great expense in fitting up the electric light, had abandoned it, and were now using daylight." Evidently the reporter misunderstood me. Although I prefer daylight myself, I was fully aware that the Eastman Company use the electric light exclusively, not only here, but at their American establishment, where daylight is as far more plentiful and constant than it is in this country. They find that by the aid of the arc light they get better and more uniform results than by daylight.—I am, yours, &c.,

22, Goldsmith-road, Acton, W.

E. W. FOXLEE.

FLASH LAMPS.

To the Editor.

SIR,—If I understand the recent correspondence on flash lamps, Mr. Hart claims an exclusive right to the use of several magnesium flashes fed by an air supply from one pneumatic ball.

It may be within the memory of the Editor of this JOURNAL that he described the blow-through flash at a meeting of the London and Provincial Photographic Association early in 1888—by the reports I see that

it was on January 5. After describing the lamp, Mr. Taylor mentioned that several lamps could be used to distribute the illumination. It then occurred to me, as it would probably to most people, that the proper method to use a series of lamps would be to have them fed from a single supply, so that the ignition should be simultaneous. Such an obvious arrangement certainly ought not to be, and would not be under a just and well-considered patent law, the subject for a patent, so that whoever happened to be the first to rush off to secure for himself a monopoly should be legally entitled to prevent others from using a plan which would surely occur to them in the course of practice. Whether such an obvious contrivance can be legally secured by patent it is not necessary to inquire just now, but it occurred to me on the evening in question that it was one of those things that some one might rush off to the Patent Office and secure to himself and debar others from using, and with this idea in mind, and to prevent its being carried into effect, I suggested that evening that when several lamps were used they should be fed from one air ball. Four days after that meeting is, I believe, the date of Mr. Hart's application for patent.

As an illustration of how surely such obvious ideas as that of connecting several lamps with one pressure ball must occur to many, there is a letter in your issue of January 13, 1888, from Mr. Hugh Reid, in which he speaks of using this contrivance. As this letter, however, only appeared a few days subsequent to Mr. Hart's application for patent, it would not suffice to vitiate it—supposing, that is, that at present such obvious contrivances can be secured; but it is otherwise with the public mention of the earlier date that I have referred to, and I think photographers need not fear the threats of being put to heavy law expenses in which Mr. Hart indulges. — I am, yours, &c., W. E. DEBENHAM.

To the Editor.

SIR,—In looking through the letters that have appeared in THE BRITISH JOURNAL OF PHOTOGRAPHY on the above subject, passing between Mr. F. W. Hart and Mr. W. England, I find one of the claims made by Mr. Hart is the attaching of several lamps by means of rubber tubing to one common centre, from which centre the whole of the lamps can be simultaneously ignited. Unless Mr. Hart's patent dates anterior to November, 1887, I claim to have fired several flash lamps at that date from one centre, using a Fletcher foot bellows as the air chamber, and to have given public demonstration of the same at the Liverpool Photographic Exhibition in March, 1888, using four flash lamps, lighted simultaneously from the one centre, and connected by various lengths of rubber tubing, the two outside lamps being twenty-six feet apart, the air being supplied by the Fletcher bellows.—I am, yours, &c.,

25, Williamson-street, Liverpool, May 13, 1889. RICHARD CROWE.

RE PSYCHIC PHOTOGRAPHY.

To the Editor.

SIR,—Miss Power should, I venture to think, have answered my notes before, that they might have been more conveniently read side by side with her own letter. I wrote exactly, truthfully, and somewhat fully of what transpired at our interview, and as Miss Power cannot say the report was unfair or untrue it seems strange she should consider it ridiculous or repulsive. She mentions two mis-statements, as she terms them; one that Mrs. E. gave her the spirit photographer's address. If she reads my letter she will find herself in error, as I there say distinctly she "received a communication from the spirits"—Mrs. E. being the medium, and that is decidedly what Miss P. told me. Again, I never said that "phenomena" were never obtained except when the artist was present. She will, on referring, again find herself in error; I said the spirit forms were never recognisable except when he, the artist, was present. What Miss Power terms "phenomena" are in some cases dots or patches entirely devoid of semblance to any human being.

The lady says she accepted Dr. Norris as the Editor's deputy. The Doctor is himself a spiritualist, and has been physician to Miss Power's family for years, but I believe there are other and ample reasons why he will not act, and it was to give the lady an opportunity of demonstrating that I came forward; the failure has been totally hers, not mine.

The age does require proof, as sagely reasoned by Miss Power, and the statement she made to me that she had seen "lumps of coal passed through a table-cloth without leaving a hole," and had "had letters brought from one room to another, though all doors and windows were securely closed, and had even felt the spirit hands that brought them," I look upon as statements only, but they illustrate the receptive power of the lady's mind.

Finally, Miss Power apparently objects to be looked upon as a "victim." May I ask in what other light she would desire to be looked upon? —I am, yours, &c., EDWIN C. MIDDLETON.

ART AND PHOTOGRAPHY.

To the Editor.

SIR,—Your critic on the Glasgow Amateur Photographic Exhibition kindly notices my pictures in flattering terms; but in reference to one of them, titled *On a Tree Top*, says, "This is a picture of two ladies evidently balancing themselves on a bough, and Mr. Clark has fallen into an error of turning the eyes in the opposite direction to the

head." It would be more correct to say in a side direction. However, I wish to point out that this is no error, but is the very thing that gives character to the picture. I am well aware of the conventional rule that one finds in many so-called photographic manuals for guiding amateurs and others how to pose their models to have the eyes in the same direction as the head. It shows, however, that an artist should not be guided always by such a conventional rule, but rather by that artistic instinct that makes him feel the best position is the most natural, and that if he goes by the conventional rule, he will get nothing but that wearying repetition of position that renders so many portraits quite commonplace. It should be the effort of the artist to avoid this.

It is no error to do as I have done; on the contrary, it is quite a usual practice with the greatest painters of ancient and modern times, as will be found by looking at the works of Rembrandt, Van Eyck, Frank Hals, Greuze, Millais, and many others. I have at hand a splendid work on *Flemish and French Pictures* by the great critic, F. G. Stephens, and I find, out of the seven portraits illustrated by such artists as Carolus Duran, Van Eyck, Frank Hals, Rembrandt, Wattenau, and Greuze, no less than five of these portraits happen to look in a different direction from the head, and that two only look in the same direction.

I would not have troubled you with a personal reference to my work, were it not that, as a very humble amateur, I have taken to photography as a pastime, willing to learn and eager to improve; but my love of art, and the study of it, began long before I had taken my first negative, and I find that it is the artistic side of photography that requires, and is receiving in the present, more attention than it has in the past, and it should be the aim of all photographers to increase their knowledge of the principles of fine art.

At present most of the manuals that have been issued by photographers dealing with this side of the question of picture making have laid down rules which only seem to lead astray, and it must be admitted that studying the great masters is better than blindly falling into the pitfalls that cast-iron rules offer to the unwary. You were good enough to reprint in your last *Year-book* a paper which I read before the Glasgow Amateur Association, in which I endeavoured to show how "Composition" can be applied to photography, but although I then attempted to lay down some rules for the guidance of amateurs, there is no one who is more conscious of their insufficiency than I am, and no one who would wish to direct the photographer more to a study of the principles upon which the great masters composed their pictures by studying their great masterpieces, and endeavouring to analyse the motives of their work by seeing the originals. Apologising for trespassing so far on your space— I am, yours, &c., DAVID R. CLARK, M.A.

Clairmont, Pollokshields, May 10, 1889.

"SWEATING."

To the Editor.

SIR,—As one holding the position of branch manager in the leading firm of photographers producing photographs at popular prices, and who has, among others, been made the object of a scurrilous and inaccurate attack by "Fair Play," in his letter appearing in your issue of April 12, and consequently being in a position to speak with authority from a knowledge of the working of that firm, I beg being permitted through the columns of your JOURNAL to reply to the statements contained in "Fair Play's" letter, and to thereby dispel from the minds of those likely to entertain such ideas consequent upon the perusal of that person's letter that any such malpractices as that of sweating exists in the firm to which I have the good fortune to belong, and which has been so pointedly alluded to by "Fair Play" when he states that the principal firms of sweaters have their studios not a hundred miles from Regent street.

The one thing which must strike the most unobservant reader of "Fair Play's" letter is that from beginning to end it bears upon it the impress of spleen and rage fostered and brought about by an inability to compete with those he so courageously attacks (and that, too, under the regia of a *nom de plume*), either in professional skill or business ability.

His statement that the assistants of such firms are provincials (thereby meaning that they, the provincials, are fools and incompetent), and are galled into an acceptance of service, is, to say the least, astounding; having in mind the fact, as every one possessed of common sense must, that before proceeding to the acceptance of employment they would first make sure of the amount of salary and the permanency or otherwise of the situation in view.

"Who would employ them after being in the employ of such firms?" asks "Fair Play." To that I make answer, No good man need ever fear being out of employment. "Fair Play" also gives it that the principal firms stigmatised by him as sweaters are capitalists, thereby inferring that they can produce photographs at a far less price than can be done by private photographers. Just so, and such being the case might I ask, Where is the necessity for sweating by these firms?

Now, touching the accusation that the *employés* of those firms coming under the ban of "Fair Play's" wrath are paid starvation wages, and made work long hours, may I inform "Fair Play" that in one firm at least, and that the most important, that far from such being the case we are, on the contrary, better paid, and have a less number of working

hours than a great many houses I wot of, styling themselves first class, impose upon their assistants.

I do not speak from hearsay when I make this assertion, for I have had the honour of being employed as first assistant in two of the leading firms of photographers, and am considered not only competent in my work, but a specialist in two branches of our profession, and feel it no degradation, but, on the contrary, an honour, to be an *employé* in a firm, who, by good and skilful workmanship, combined with business acumen, brings to their knees such as "Fair Play."

Now the motive for "Fair Play's" attack must be apparent to all, but the means which he brings to his aid in his endeavour to crush his more successful rivals merits the severest form of punishment, both at the hands of the law and his fellow-photographers.

When it is borne in mind that the public is at the present moment agitated by the disclosures made before the Royal Commission appointed by the Government to investigate the nefarious system of sweating, and that that public would visit with the gravest displeasure and a withdrawal of their support any firm, photographic or otherwise, working their *employés* under such a system, one cannot help feeling for such a person contempt and loathing, and a sorrow that our profession should have among its numbers one capable of such conduct as that of endeavouring by such means to bring into odium and disrepute those whom otherwise than by a cowardly and treacherous attack from behind the protection of a *nom de plume* he is incapable of injuring.

I am bound to say, in conclusion, that a finer adept in the art of calumny than "Fair Play" it has never been my misfortune to come across, and would therefore strongly advise his studying and taking to heart those lines commencing with, "He that steals my purse steals trash," and ending with, "But leaves me poor indeed."—I am, yours, &c.,

JUSTICE.

London, May 14, 1889.

[On Free-trade principles a firm or an individual has a perfect legal right to charge as low a price for their productions as they choose, and this altogether irrespective of its influence upon others of the craft or profession. We are in entire ignorance of what firm or firms "Fair Play" may have had in view when he wrote, but as regards the "sweating" element, it cannot evidently have been that of which our present correspondent is manager.—ED.]

PHOTOGRAPHY AND CUSTOM-HOUSE AUTHORITIES ABROAD.

To the Editor.

SIR,—In your issue of the 19th of last month, I was most pleased to read the letter from Mr. A. Levy on the subject of the Custom Houses on the Continent respecting photographic plates.

Although only an amateur (fresh to the work compared with others) I have had a good many dozen plates through the Customs, both in Belgium and Germany, but have had no experience in France, as I am sorry to say I have as yet had no chance of doing work there. But in the first two named I have had no trouble whatever. In Germany they are a little more inquiring than in Belgium, but a little explanation sets matters all right, even with the most unreasonable official, when you are careful about the way you go about it.

You will find your trouble in Belgium *nil*. A few months ago I had about eight dozen Ilford plates sent over; the box they were in was never touched and there were no inquiries made, so the box was forwarded straight to my lodgings without being opened.

Rather than have anything to say against the Custom Houses on the Continent, I shall always stand up for them. I may say I, for one, have found them most obliging and well-disposed to the unfortunate English amateur. Hoping that this cry of avoiding one country more than another on account of the Customs will soon die out and be a thing of the past—I am, yours, &c.,

EDWARD E. LAWSON.

32, Rue de l'Olivier, Antwerp, May 15, 1889.

IN RE "JUNIUS."

To the Editor.

SIR,—With the view of demonstrating in a practical manner the kind of glass I propose for the sensitive film, I send you by parcel post a 7½ x 5 glass plate; one side marked "x" is the side I propose to coat with the emulsion—it is technically called "smoothed" by glass makers. The other side is fine ground for the back to be worked upon (if necessary); this should remove any "ambiguity."—I am, yours, &c.,

Waverley, Alexandra Road, Birkenhead,

JAS. ALEX. FORREST.

May 13, 1889.

[Glass of this nature will certainly answer well the purpose indicated.—ED.]

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—On Thursday next, May 23, Mr. Valentine Blanchard will give a demonstration of his new platinum toning process.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, May 22, 1889, will be on *The Keeping Qualities of Photographic Chemicals and Bromide Plates*.

Exchange Column.

Exchange 12x10 double extension camera for 15x12 triplet Ross or Dallmeyer.—Address, CARNELL, Photographer, Nottingham.

Will give lantern slides of Irish scenery and a half-plate ash folding tripod in exchange for dry plates, half-plate size.—Address, EDWARD J. HUGHES, Graigue, co. Kilkenny.

Wanted, half-plate camera, portable; exchange, elegant pair of hand-painted plaques or other valuable works of art. Approval.—Address, LEWIS MILTON, 12, Paul-street, Warrington.

I will exchange a quantity of medallion rims, glasses, and backs, complete, for quarter-plate camera and lens.—Address, PHOTO, 3, Springfield-villas, Palace-road, Bowes-park, London, N.

Answers to Correspondents.

PHOTOGRAPHS REGISTERED:—

J. A. Kay, Bolton.—Three photographs of Rev. H. Enfield Dawson.

D. B.—There is no difference between the permanence of ferrotypies and glass positives. The constitution of the image is alike in both.

GEO. FALL.—Three inches is too short for the focus of a detective quarter-plate camera. Much better to have it nearer to twice this focus.

HOSPITAL.—The camera marked No. 2 on your list is to be preferred on account of its great extension. The lens No. 1, by same makers, will suit it admirably even when used with only one of its components for distant views.

SYMMETRICAL.—The picture would be very good were it not for the clouds. These are printed far too deeply, and, moreover, they are not suited to the subject. The lights on the clouds are diametrically opposite to that falling on the landscape.

S. J. W.—To avoid the cold tones in enlargements you must give a *very* full exposure, and employ a very much diluted developer containing but a small proportion of iron, and that well restrained with bromide. Of course, under these conditions the development will be more protracted than usual.

VINIE.—The delay of a week arises solely from your own negligence of the announcement regularly printed at the head of this column. If A has a copyright in the portrait, and B copies and sells it, A can most undoubtedly enter an action against B, even although the copy he purchased was not marked as being copyright.

J. R. WILSON.—Make a deal camera of the very simplest form, and after you find it to work well enclose it in a case of a suitable form. It is absolutely impossible for us to give you detailed directions, as the element of personal ingenuity must be brought largely into requisition. But if you submit your plans to us we may then be able to advise.

"BUTON."—Your prints must be made from very thin negatives, and contain but little gold when toned if they will not stand treatment with warm water. When the size is removed from the paper they have little tendency to float on the surface of the water, but this should not injure the print. Iodide of starch is the most delicate test for hyposulphite.

A. THOMAS writes as follows: "I find in mounting prints on glass with gelatine that the spotting comes off in the warm solution. I have tried using plenty of gum with the colour, and, at the suggestion of a friend, tried mixing the colour with albumen, but still it comes off. Is there any means of preventing this?"—The best plan is to spot the pictures which have to be mounted in optical contact with glass with oil colour. The tube colours simply thinned with spirit of turpentine answer every purpose.

F. COOP writes as follows: "I purpose taking a cruise along the western coast of Norway up to the North Cape in July; I shall take my tripod camera and a touch detective. I should esteem it a great favour if you or any of the readers of your valuable paper would furnish me in an early issue with any hints as to exposure, objects to photograph, or any information of use on such a trip."—Perhaps some reader who is familiar with this part of the world will kindly favour our correspondent with his experience.

W. T. HAMMOND writes: "While printing off some negatives a few days since I had the misfortune to get some wet with rain, and the result is bad silver staining on the bottom of one of them. Will you kindly inform me the best method of endeavouring to get rid of this stain, as it is a negative I value? I have looked through the JOURNAL for about twelve months back, but have not dropped on the remedy, though I remember reading something about it. Your reply in next issue would much oblige."—If the stain is chiefly on the surface, gentle friction with alcohol, rubbed on with the finger, will sometimes remove the stains entirely.

F. STANLEY DOBSON (Melbourne).—There is no question that in taking interiors very much better results accrue if the plates are backed; also, that in many outdoor pictures their quality would be greatly enhanced if the plates were similarly treated. But we very much question if plate manufacturers can be induced to send out their plates ready backed, even at an enhanced price. They look at the matter from a commercial point of view, and several we have approached on the subject declare that it would involve so much extra trouble that it would not prove remunerative. The only way we can see at present is to treat the plates yourself, although it involves some extra trouble. But for this the improved results obtained will amply repay, particularly in taking interiors, or when the plates are thinly coated with bromide.

No. 1516. VOL. XXXVI.—MAY 24, 1889.

IRREGULAR DEVELOPMENT WITH HYDROQUINONE.

SOME little time back Mr. Lyonel Clark called attention to a peculiar irregularity in the action of hydroquinone in development, and the same subject was commented upon by our correspondent "Junius." The particular kind of irregularity noticed by these two observers seemed to lie in a tendency on the part of the developer to commence its action at the edges and to gradually extend to the centre of the film; and, if we remember rightly, the phenomena in both cases were confined to paper proofs.

Since the publication of the comments alluded to, we have ourselves noticed an apparently quite distinct kind of irregular action, and in our case, too, it seems to affect paper, or rather films spread upon paper; if not solely, at least in a far more marked degree than we have ever noticed with emulsion upon glass. The form of irregularity is so marked that we have been induced to study it somewhat carefully, and though we have not yet been able to arrive at any definite decision, we are of opinion that further investigation may most probably lead to the establishment of some important facts with regard to hydroquinone as a developer; and with a view of enlisting the aid of some of our experimentally inclined readers, we propose to describe the case, and briefly state the opinions we have so far formed thereon.

In the first place we may state, as having a somewhat important bearing upon the case, that the paper with which we have chiefly or in its most intensified form noticed this peculiarity is that known as "Alpha," which, as most of our readers are aware, differs most materially in its character and behaviour from the general run of "gelatino-bromide" papers, containing as it does at least a large proportion of chloride. We mention this simply as tending to support the hypothesis we have formed. We may also say that the particular paper we have used is not new, nor have we any reason to suppose it is very old, but, at any rate, the irregularity is of so definite a character that we can under no circumstances attribute it to partial decomposition or deterioration of the film.

Upon submitting a piece of exposed paper to the action of the developer, which may consist of hydroquinone, with either of the carbonates or hydrates of sodium or potassium, and *without* bromide, the picture will appear gradually and progress steadily, and with moderate rapidity, until the best effect producible, without restraining bromide, has been obtained, and very probably no abnormal appearance will be presented. But if the same solution be applied to a second proof to which the same exposure has been given, the development will, in the first place, be much slower both in starting and in progress; then, when a certain stage is reached, and before full strength

has been attained, or in case of a short exposure before the details have been got out, the deepest shadows of the picture—the hair, the folds of drapery, and the shades of the face—will commence to exhibit a peculiar patchiness, and, as development proceeds, this becomes more and more intense, and gradually spreads until, if continued long enough, it extends to the whole image, even to the lightest details.

If pushed to the utmost extent, as described, the image after fixation will exhibit an abnormal density far in excess of anything suitable for a positive, but if the development be arrested at an earlier stage, and the proof fixed, it will exhibit the appearance of bearing two distinct images of a totally different character. The half tones and lighter portions which have not reached the patchy stage will partake of the ordinary character of the image produced upon "Alpha" paper, while the darker parts will be found to possess an intensity and blackness rather suggestive of a heavily salted and over-developed negative paper.

It will be observed that a freshly mixed developer without bromide exhibits little or no tendency to this peculiarity, but that after the solution has been once used, and consequently derived a certain quantity of bromide from the developed print, the irregularity or double image makes its appearance, and each successive employment of the same solution produces it in a more marked form. If bromide be added to the fresh developer, the first application produces the effect, so that we see the bromide in some manner exercises a direct and powerful action in the matter.

After many experiments and some careful thought, we have arrived at the following conclusions, which we put forward merely as an hypothesis by which the phenomena may be explained. It may be taken as an almost undoubted fact that the "Alpha" film contains a compound silver salt; that is, that it is not composed of pure chloride of silver. Assuming this to be the case, it is easy to believe that hydroquinone possesses widely different developing powers upon the different salts, and also that free bromide exhibits a disproportionate modifying action, and that consequently two distinct images are developed, each having for its basis one of the elements of the compound.

To illustrate more clearly what we mean, we will suppose a film composed mainly of silver chloride with a small trace of silver iodide, which we take as presenting the greatest probable chance of different action. We are not, of course, confined to that combination, nor, indeed, to any compound of the haloids, as several of the insoluble silver salts—such as citrate, tartrate, oxalate, carbonate, phosphate, and a host of others—may be included in the list of possible variations. For our purpose, however, we will take a chloro-iodide film.

Chloride of silver, as is well known, is more easily reduced

by our known developers than either bromide or iodide; indeed, it was for some time considered practically impossible to develop an image by means of alkaline pyro upon plain chloride of silver. Hydroquinone, however, amongst more modern developers, has been found capable of use with silver chloride, so that we may imagine the first delicate image that is produced to result from the action of the developer upon the chloride portion of the sensitive film. But as its action is continued, the iodide or other element comes within its power, and is reduced to form an image of so totally different a character, that it entirely overpowers the more delicate one that preceded it.

With regard to the action of the bromide in the matter, we may assume that its restraining action is proportionately greater for silver chloride than for the iodide or other salt, and that, therefore, in its absence, or when present in only small quantity, the chloride image is developed to full strength before the second image commences to appear; but that when the restraining action comes into force, it acts so powerfully upon the chloride that the second image is able to overtake and overpower it.

We put this forward merely as a feasible explanation of a most curious phenomenon, and shall be glad if any of our readers who may have noticed the action will offer further suggestions. Meanwhile, we may point out that if hydroquinone really does possess so distinctly a discriminating action with the different salts of silver, an entirely new power is placed in the hands of the plate maker, who will thus be enabled to vary the character of his films for special purposes to a far greater extent than hitherto.

The question is certainly worthy of further investigation, and we hope before long to be able to say more upon it.

THE UTILITY AND APPLICATION OF COMBINATION NEGATIVES.

In two previous articles we have shown different methods by which two or more negatives may be made into one. In those articles, although it was not attempted to describe all the plans by which the same end might be accomplished, sufficient was indicated by which any one of average ingenuity might accomplish almost anything that occasion may require in the way of combination negatives, no matter what may be the subject.

In the former articles we treated only the combining of negatives, so as to include laterally a larger amount of subject than could be got in a single negative, such as in making a panorama. But it is manifest that what can be done horizontally can also be done vertically, or in addition to what is done horizontally. For example, four negatives may be combined—two vertically and two laterally. It may be urged that a picture produced under these conditions will not be correct in perspective. Granted. But if the thing be not carried too far—made to embrace an abnormally wide angle—the error will be so trivial as to pass quite unnoticed.

It often happens that a landscape has to be taken in which there are, say, some distant mountains with the sun shining upon them, while there is a very dark foreground which must be included. Now, if the exposure be timed for the brightly illumined distance, the dark foreground will be under exposed. If, on the other hand, it be made for the foreground, then the distance will be overdone. Much, it is true, may be accomplished in the way of judicious local development, but there are, at times, circumstances under which this treatment will not

produce all that is desirable. If, however, two negatives be taken, exposing one for the middle and extreme distance, and the other for the immediate foreground, then, by taking the best portions of each and combining them into one picture, a successful result may be obtained.

Some may possibly be inclined to argue that this is not a legitimate proceeding, and that, moreover, the resulting picture would not be a harmonious one. To the first point we reply "not proven," inasmuch as the aim of the artist is to get the best possible result, and therefore the end justifies the means whatever they may be. As to the second point, this will all depend upon the judgment of the operator. Here is a power at command for use in extreme cases, but, as a matter of course, it must be applied with discretion. If the foreground were made as light as the distance, for example, it goes without saying, the result would be simply ridiculous.

Here is another example of how combined negatives may prove advantageous. In taking interiors it often happens that one portion of the building is much better lighted than another, and what would be the proper exposure?—that for one part might be either too much or too little for another. But by a combination of two negatives the trouble may be overcome. How very much better would many photographs of interiors be if some of the windows—which, as a rule, are always more or less overdone, or show a considerable amount of halation—were taken on a separate negative with the right exposure for them, and then substituted for those in the first! In such cases the junctions are not at all difficult to hide.

In portraiture, too, much may be accomplished by the aid of combination negatives. For example, in taking several persons in a group, it frequently happens that one or more of the portraits are unsatisfactory by reason of the expression, or, perhaps, from movement. This not infrequently leads to the condemnation of the picture, or, at least, to a limitation in the number of duplicates required, as most professional photographers know to their cost. If, however, a second or third negative is taken, the chances are that those portraits which are unsatisfactory in one may be just the reverse in another; while, on the other hand, figures which are good in the one may be the contrary in the other. The larger the number of persons included in the picture, the greater are the chances against a successful whole being obtained. If two or more negatives be taken, it is then easy to take out any faulty portrait and replace it by another from either of the other negatives, for it is seldom that the same portrait will be defective in all alike.

In outdoor groups especially may the power of combining negatives sometimes prove a great acquisition. It is no unusual circumstance that, say, a wedding party, or, possibly, a cricket or football club has to be taken with a background of dark foliage, maybe an ivy-covered wall. Now, what would be the proper exposure for the figures in their light costumes will be far too little for the background. Hence the latter is generally sacrificed entirely, much to the detriment of the picture as a whole. There is, however, no reason why, when one or more negatives of the group have been secured, another should not be taken of the background alone. It could then be introduced in the group negative in place of the under-exposed one.

A notable example of where a combination of the above kind would have greatly improved a photograph is now before us. It is a group of a large number of Royal personages, photographed, as we know it was, under adverse conditions of light. It was taken out of doors, with shrubs and trees as a background.

The figures are fairly well-exposed, but the background is greatly underdone. This has apparently been "dodged" in the negative to prevent its printing as a heavy black mass. But this treatment has made it flat and lacking in vigour. Now if a second negative had been made of the background by itself, and this afterwards substituted for that obtained with the figures, an excellent result might have been secured. Why this was not done it is difficult to imagine, as the whole of the prints issued to the public were, we believe, made from reproduced negatives.

It is really surprising how little is actually done in the way of combination negatives, probably because so many imagine that the operations are both difficult and tedious. But this is not really the case if, as we recommended, advantage be taken of stripping films.

It has often been a matter of some surprise to us that in the establishments of manufacturing opticians, and even in those of dealers in lenses, provision is so seldom made to enable the purchaser to make trial of his lens, and see, on the ground glass of the camera at least but preferably by the more tangible test of taking a picture, just what it can do. We are pleased to be able to announce that one eminent firm of opticians, Messrs. Ross & Co., of 112, New Bond-street, have now met this requirement in a very thorough manner by having their first floor converted into a show room, to which, as an adjunct, there is attached a well-fitted dark room, containing every appliance for enabling the intending purchaser to see the nature and scope of any lens, and, by taking a negative and developing it on the spot, to secure a memento of its performance. This example, of which we cannot speak too highly, ought to be followed by every one.

We have often called attention to the fact that the atmosphere of towns is injurious to the integrity of silver prints, and that, in all probability, the sulphuric acid always present in such atmospheres was the cause, or one of the causes, of the injurious effects. Silver printing is as popular as ever, especially for small work, and we think it by no means undesirable that photographers should take some means of pointing out to their clients that to be looked upon as permanent, or even lasting, all silver prints should be protected from the action of the air. An annoying occurrence which recently came under our notice showed our suggestion to be eminently desirable. A well-known photographer, whose work is most carefully treated to ensure the utmost possible approach to permanency, recently had brought to him a panel photograph not more than two years old, but which yet showed distinct signs of fading. A long investigation failed to point out any cause for this, and the only conclusion he could come to was that the form of frame was answerable for the evil—it was the convenient and pretty form known often as the *Mora* frame, which, as need scarcely be pointed out, allows complete access of air to the picture behind it. It would be unfortunate to condemn these exceedingly effective picture holders, and we should be very glad to have opinions upon the subject by some of our readers who can speak upon it from practical acquaintance.

THAT the question of sulphuric acid in the air is no figment, may be seen from a paragraph in the *Chemical News*, quoting a medical contemporary, to the effect that every day in London three hundred and fifty tons of sulphur are thrown into the atmosphere. This quantity represents upwards of one thousand tons of monohydrated sulphuric acid, not merely wasted, but employed in mischief!

THERE are, of course, photographs and photographs, and there can be no doubt that a large number are produced which no care in etching or in preserving from the action of the atmosphere will preserve from fading, while at the same time there are others which will stand a considerable amount of careless exposure and yet appear to be none the worse. We were lately in conversation

with a gentleman who had been several years in Ceylon, and he gave us a little personal experience on the subject. Shortly before leaving this country he had his photograph taken at two different studios, and he took the *cartes* out with him. He stated that before he had been in the island three months, one of the sets of pictures had "faded into nothing," while the others (taken out at the same time) were apparently just as good when he left Ceylon, after half a dozen years' residence, as when he first brought them in. No amount of explanation about the action of the atmosphere could explain the failure of the first-named set to stand against the climatic condition of the place.

IN *La Nature* of last week there is a long and full account of the inauguration of the new establishment for judicial identification by means of anthropometry and photography, which evidently comprises an elaborate and highly-organized machinery for the prompt multiplication of large numbers of photographs in a short space of time. "On this vast site, thirty metres long and twelve wide, are found in succession—a waiting-room for prisoners; then the studio, allowing a distance between camera and lens as may be needed of from six to twelve metres; thirdly, a special room for the reproduction of documents, with object holder and camera upon rails, &c. Next, a series of rooms for each successive operation of photography—sensitising paper, printing proofs, fixing and washing positive impressions, mounting and rolling. But no retouching room, that operation being rigorously forbidden in all photographs intended for legal purposes.

MODERN modes of quick printing are adopted, bromide paper being employed of course. A method of increasing the rapidity of production and diminishing the cost consists in sacrificing the bust and the breadth of the shoulders. It is thus possible, by means of slight reduction, to group twenty of these heads upon a negative of about half-plate size—postage-stamp pictures, in fact—and, it is pointed out, twenty thousand prints can be made in a night. The reproduction is carried on in the rooms with least light, as artificial illumination is easiest and best adapted for the purpose.

It is evident that in the anxiety to facilitate the production of prints there will, under the influence of the proverb, "the more the haste, the less the speed," be liability to mishaps; but in every way these are provided against, even to the extent of having a separate worker to fix the prints so that particles of hypo may not be transferred or carried about to the production of spots.

AGAIN, too, under such conditions nothing would be more likely than the leaving open of a door, to the injury of large numbers of prints by exposure to light. This also is provided against, by a useful but not a novel manner, by avoiding the use of doors altogether. Each room is kept apart from the others and opens out into the studio by means of a kind of curved lobby or passage, with partitions on opposite sides. There is thus produced a path of a kind of zigzag section which effectually extinguishes the light, the partitions being blackened and necessitating three reflections before light could enter the room, by which time it would be so lessened that the most acute eyesight would fail to perceive it.

THE WHOLE ART OF PHOTOGRAPHY IN A SERIES OF EASY PROGRESSIVE LESSONS.

CHAPTER III.—DEVELOPING A NEGATIVE.

It is perhaps well that at this stage we should apprise the reader, who is presumed to be ignorant of photography, how to take a negative by the one popular method, that is, by means of commercial dry plates.

The camera and lens are supposed to be on hand, and to be made or supplied by a responsible firm. The plates are further supposed to be supplied by a reliable firm, and one of them is still further supposed to have been, by aid of a feeble light from a ruby lamp, transferred from its package to the dark slide. Focus an image

sharply, using, if necessary, a magnifying glass to this end. Draw the dark shutter from the slide, and expose by uncapping the lens. How long? Everything depends upon the subject and the light. If a well-lighted landscape, the exposure must not exceed a fraction of a second. If a figure or group be the subject, the duration of the exposure may be anything from one second to several seconds, this depending upon the intensity of the light—which is supposed to be, in this instance, of a subdued character—and the aperture at which the lens is worked. In a back garden, entirely shaded from the sun, a good negative is frequently obtained with an exposure of one second when the lens is working at $f/8$. But experience alone can dictate the exposure that affords the best result. Anyhow, the plate, having been exposed and brought into the developing room, is removed from the dark slide and placed face up in a flat tray, which should not much exceed its own dimensions. Still protected from all light save that of the feeble red lamp, the developing solution is poured over it in quantity sufficient to ensure the surface being properly covered.

But here we must hark back. There are three distinct and different classes of developers that may be applied—pyrogallie acid, iron, and hydroquinone. When we say that each of these, even among experts, has its own advocates, the reader will naturally conclude that after all there cannot be any great degree of difference—not enough, at any rate, as to very greatly influence him in the choice of the one he is to adopt. This conclusion will not be far from being correct. We will, however, place before him formulæ for compounding developers of each class, and shall make a passing note relative to the behaviour of each, after which each is free to select his own.

We have placed pyrogallie acid in the first position. It is that which is probably employed by the greatest number of operators at present. It is a system which will invariably afford satisfaction when worked with even the most moderate amount of intelligence. Pyrogallie acid is the reducing agent, but it must have allied with it an alkali, for what particular reason we shall not stay here to inquire. If it is to be kept in solution it must also have dissolved along with it some body that will prevent it from oxidising, for pyrogallie acid when dissolved in water without anything else will soon become of a dark-brown colour, and be unfit for use. But at this stage we do not wish to enumber the practitioner with much chemistry, and shall therefore recommend him to make a developer as follows:—

Make the solution as follows:—

Sulphite of soda	6 ounces.
Hot water	32 "
Pyrogallie acid	1 ounce.

(Having dissolved the sulphite of soda, add sufficient citric acid in solution to cause a piece of blue litmus paper inserted therein to become reddened.)

Into another bottle dissolve:—

Carbonate of soda	3 ounces.
Carbonate of potash	1 ounce.
Water	32 ounces.

Note here that the carbonate of soda in this formula is not baking soda, popularly so called, or bicarbonate of soda, but the mono-carbonate as used for washing purposes.

When about to develop, mix these in equal proportions with two parts the bulk of water, or, if the weather be very hot at the time, even a greater proportion of water.

Now watch the progress of development. If the image comes out too quickly the probability is that too long an exposure has been given, more particularly if the deep shadows come out very soon. In a well-exposed plate everything should proceed evenly, the highest lights first of all, these followed by the middle tints, and, last of all, by the deep shadows, which should be slow to appear.

A rather weak developer is the most manageable, because a certain time elapses between each of these parts making their appearance, and time is allowed to remove the plate at any stage. If the high lights only appear even after a considerable time is allowed for the developer to act, it may be concluded that the plate has not received sufficient exposure.

But an under-exposed plate may be got to yield up its dark details by employing a rather weak developer, and allowing it to act for a sufficiently long time. On the contrary, a plate that has had a too-long exposure may be made a tolerably good printing negative by removing the developer by copious dashes of water, and applying another in which the pyrogallie acid shall predominate in a much larger degree than that indicated above; for, speaking in general terms, pyrogallie acid favours intensity, while the presence of an alkali favours detail. The knowledge of this will enable the beginner to so modify his developer as to utilise the latitude which all dry plates possess as regards exposure.

Again, the addition of a retarder, or what is known as such—for instance, a solution of bromide of potassium—will prove a powerful weapon in one's hands. The presence of such a body in the developer retards the action of the developer as between high lights and deep shadows; hence it is well to have always ready at hand a dropping bottle containing a solution of this class of salt, to be employed when necessary. A solution of the strength of ten grains to the ounce of water will be found useful.

It will thus be seen that, by the exercise of a little judgment, the pyrogallie developer may be adapted to meet all contingencies, except that of a very much under-exposed plate, by merely modifying the proportions in which the pyro and the alkalia are relatively mixed.

Ammonia is extensively employed instead of the fixed alkalia just mentioned; but, in the hands of a beginner, we do not consider it quite so good as that given. Both liquor ammonia and the ammonium carbonate become rapidly impaired in strength, unless kept in a closely stoppered bottle from the atmosphere, whereas the other carbonates suffer so little change that a large quantity of solution may be prepared at a time, in the certainty that it will remain good up to the last drop.

In selecting the soda-salt for mixing with the pyrogallie acid, special care must be taken that it is the sulphite and not the sulphate that is employed; and it is also to be noted that the sulphite, when kept in a crystalline state and exposed to the air, decomposes and becomes valueless as a preservative for the pyrogallie acid.

ON THINGS IN GENERAL.

PERHAPS "Junius" is right in calling attention to my remarks upon cloud negatives, as some readers might imagine my words to mean that such negatives taken from an attic window would answer all purposes, an idea quite contrary to my intentions. What I wished to lay stress upon was the fact that for a large proportion of pictures exhibited with printed in skies, attic-taken negatives would suffice. I go much farther than this. I say that very many photographs with double-printed skies, seen in our exhibitions, would be far more true to nature if a cloud negative had been used that had been taken from an attic window, for then by no possibility could such scientific absurdities or such artistic frauds be perpetrated as is far too often seen on the exhibition walls. Free studies or views of picturesque buildings occupying, perhaps, an angular altitude of fifteen or twenty degrees, and furnished overhead with lovely clouds, perfect poems—in themselves—that under no conditions whatever could be seen in such shapes at an altitude of more than fifteen degrees above the horizon. This is a subject upon which I feel most strongly. Several years ago there was exhibited at the Pall Mall Show, by one of our leading lights, a beautiful landscape with figures illuminated from one direction, and clouds lighted from the opposite; yet, I vow, such a drollery gave me less offence than one of the class I speak of, for it was evidently an accident of a character that I have seen paralleled in a clever oil painting; while in the former case it was crass, wilful ignorance, or worse, deception—prettiness of effect obtained by a piece of pictorial mendacity, all the more nefarious because it would not be readily found out. Still I end where I started: it would not do to employ an attic negative for all purposes, for then an opposite error would be introduced.

The new celluloid plates should be admirable for cloud negatives, as they answer even for portraits when printed with the film outwards, and there is then but a trivial difference that many would not notice, and with clouds it would be quite imperceptible, and the stock of

negatives required would be thus reduced by one-half, as the question of right or left lighting would solve itself by the mere reversing the plate or tablet on the printing frame.

The flash light controversy still continues well into the margin of summer; but I am inclined to believe that far more will be expended in patents, and patent contrivances, for burning the light than ever will be made out of the pictures produced by its aid. I do think that the pyrotechnics will, even yet, win the day; for, as has been demonstrated, they can be made both innocuous and non-poisonous. Some of my readers may not have noticed that at one of the American meetings an ardent exhibitor was so determined to show the harmlessness of his particular compound that he actually swallowed enough of his own magnesium flash powder to have sufficed to take a portrait with. It is no uncommon thing to take magnesium oxide inwardly, as many of us well remember happening in the days of our childhood; but the metal itself, and with other things, is a brave undertaking. I should prefer "gun-cotton" to "gun-paper," and the ready prepared gun-sawdust—to coin a word—to either, for the latter you can buy ready prepared, as I think I once before stated, while the loose texture of the gun-cotton would lead to a quicker explosion than explosive paper, seeing that as a certain amount of oxygen from the air is used up by tri-nitro-cellulose—to give the proper designation—when it is exploded by ignition it can obtain it more quickly from the increased area of the pulled-out mass of cotton than from the flat sheet of the explosive paper, which imprisons, comparatively speaking, no air.

Some one recently asked, at a meeting of one of the London societies, if any one had practically adopted quinol as a developer to the exclusion of pyro. I should, on my part, like to ask if any one has adopted orthochromatic plates to the exclusion of the ordinary kind for professional portrait photography? So much has been said about the great advantages these plates, even without the screen, possessed in the rendering of flesh tints, and actually in considerably enhanced rapidity, that one might have expected ere now that the orthochromatic plate would be crowned king of the studio amid shouts of "*Le roi est mort! Vive le roi!*" Yet only the other day, at the Paris Academy, we find a member coming forward to show that with well-selected coloured screens every effect desired could be obtained from coloured objects, and as to screenless productions, no farther back than the 2nd instant, Mr. William Coles, at a London and Provincial Photographic Association meeting, actually brings two portraits of a freckled sitter, one taken with "ortho," and the other with ordinary plate, and it is a complete puzzle to find out which is the better in respect of suitable rendering of the freckles.

By-the-by, I noticed Mr. Swain's denial of the use of a particular photographic purpose in producing the blocks for *Punch*: he is, of course, literally correct in his statement, but his letter read without comment would be apt to lead the unwary astray. True it is that in *Punch*, and other magazines, the highest class of work is done by woodcutting; but it is also true that in *Punch*, as well as these others, photography is largely utilised in producing the illustrations. Before its general adoption the usual mode of procedure for producing an illustrated block was for the artist to draw directly on to the wood (and a beautiful surface it presents for working upon). That was the last of the drawing, as all the whites were cut away so as to give the lights in the print, and the wood left standing for printing the blacks. No matter what kind of a mess the wood engraver made of his work, there was no direct proof; the drawing was destroyed. By the aid of photography the drawing made on paper can be reproduced by photography and placed on the wood, only the photograph being destroyed, with the double advantage of a perfect check upon the engraving work, and a cheque in hand for the sale of the original picture.

FREE LANCE.

ORTHOCHROMATIC PLATES IN COPYING OIL PAINTINGS.—I.

SINCE the introduction, in a commercial form, of a bromide of silver dry plate which has been specially treated, either in the formation of the emulsion or at a later stage, by subjecting the plate to a bath of colouring matter whereby the plate is made more sensitive to the yellow and red rays, undoubtedly much has been done in the way of

placing in the hands of professionals and amateur gentlemen a power which in days gone by was certainly beyond their reach or "ken," and what was often attempted in the past in the way of photographing oil paintings, or other objects where a variety of non-actinic colours existed, and which most frequently resulted in only partial success, if not indeed complete failure in many instances, now becomes an operation which, with the exercise of a little ordinary care and thought, after some practice, is almost certain to yield results at once satisfactory and pleasing.

Any one, however, who for the first time takes it into his head to go in for copying oil paintings or other similar subjects which are composed of various tints of colour, so as to render necessary the employment of a colour-corrected plate, must not imagine for a moment the whole secret of success depends upon the employment of a film specially so prepared, such an opinion is at once false and erroneous; and should a beginner set to work without first giving any thought to other matters which are quite as essentially necessary to the ultimate success as the employment of a specially prepared plate, failure is sure to be the result, with the consequent irritation depending thereon, which very likely will debar the party from deriving much pleasure in this class of work in the future.

In the few remarks which I propose to offer on this work, I shall endeavour to treat the subject in a purely practical way, and strive to point out a few of the many pitfalls which a beginner is most likely to fall into when commencing the practice of this most attractive branch of photography. As to the interesting nature of this class of work, I think but little will be required from me to show how attractive such a branch of photography must be to very many amateur gentlemen who might often feel desirous of treading on pastures somewhat new; while, on the other hand, I imagine there are still not a few professionals who even yet know but little about the employment of colour-corrected plates for the copying of such subjects as oil paintings. True it is that even in the good old collodion days there were those who knew something of the difficulty attendant on this class of work, and who even then were not unacquainted with the employment of coloured screens to cut off the undesirable rays, still I imagine the number of those who but seldom are required to do this class of work in their business are not few, and hence when the time does arrive that they are called upon to do such class of work they are not just at their ease when setting about it. To such also I venture to humbly address a few remarks in the hope it may help them to overcome some of the difficulties.

I was forcibly struck quite recently when being present at one of the charming popular limelight entertainments which have become so famous in Glasgow, chiefly through the instrumentality of the Glasgow Photographic Association. On the occasion in question, Mr. W. J. Finlayson, of Johnstone, was the lecturer, and during the course of the evening Mr. Finlayson made a fresh departure from the usual use and went on such occasions by interspersing among the set of slides which he selected for the evening's entertainment a good many which were copies from some of the finest paintings of both old and modern masters. To my mind, such pictures were not the least attractive of those which were projected on the screen on that occasion, and I know of several of those who were then present that at once made up their minds to go in for a shy at the copying of oil paintings and other pictures which they fancied, and afterwards make lantern slides from their negatives.

So much, therefore, for at least one form of attraction attending such work.

Perhaps, first and foremost, the first question that a beginner will set about deciding, is the best way of getting possession of a supply of suitable colour-corrected plates, and wonder whether it is better for him to prepare them himself or to acquire those prepared by the manufacturers. Undoubtedly, within recent years, much time and thought has been given to this subject by many enthusiastic experimentalists, and those of my readers who had the good fortune of being present at the lecture which Mr. Bothamley delivered before the members of the Photographic Convention, assembled at Glasgow the year before last, must have experienced much that was instructive on this point of the subject, and derived no little benefit from the very complete and lucid description he gave at the time as to the action of the various dyes employed by him in securing the widely different results as shown by him on the screen before the very large audience then assembled. I therefore feel I cannot do better, at the outset of this article, than to recommend those desirous of fully understanding the theory of this subject to become possessed of the reports of Mr. Bothamley's lecture delivered then, and also those given to the public on more recent occasions by him in which he fully treats on this part of the subject.

But, after all (although it is, in my opinion, most desirous that such

knowledge should be possessed by all undertaking this work), is it absolutely necessary that amateurs and professionals should go to the extra bother and worry entailed by preparing a colour bath, and dipping and afterwards drying their plates from such? And although this operation does not of necessity entail much time or even trouble when the operator is possessed of special advantages in the way of a large and commodious dark room, so as to permit of an easy means of drying being employed, still I feel that among the large number of those likely to undertake this class of work, such would, in a great measure, tend to debar them from the practice of it, were such preparation of plates an actual necessity on their part.

Luckily, however, the public are now supplied with these plates of such excellent quality, that indeed no amateur or professional either, for that part, need bother himself about preparing his own supply.

T. N. ARMSTRONG.

PHOTOGRAPHIC INDUSTRIES.

NO. 1.—WATSON'S CAMERA FACTORY.

THE firm of Watson & Sons, 313, High Holborn, London, is now of a respectable age, having been established in 1837.

For a considerable period it was associated with the sale of second-hand optical and philosophical apparatus; but as photography advanced, the then senior partner, the late Mr. W. Watson, had sufficient acumen to foresee the growing importance of the young art, and to throw much of his energy into its direction. To this end he, about eighteen years ago, entrusted his son, Mr. Thos. P. Watson (now the head of the firm), with the entire control of the photographic department, and under his management the business gradually threw off its excrescences, among others that of a lucrative high-class gun and sporting trade, now transferred to other establishments and other hands, and assumed the form of a complete optical establishment in which photographic apparatus occupied a leading position. This department, also, has been amenable to the law of evolution: for whereas it was originally confined to the sale of appliances made by others, the apparatus is now, and has for some time past been, made in its entirety by the firm, who have special factories devoted to this purpose, one of which, that of photographic cameras, forms the subject of this article.

This factory occupies a four-storey large building, and is situated in Fulwood-riots, a *cul-de-sac* off Holborn and directly opposite to the shop and sale rooms. Remembering the last visit we paid to the Watson factory, when it was situated in Dyer's-buildings, Holborn, as recorded in our JOURNAL of October 22, 1886, we could not but be struck by the great advance that had taken place between the *then* and the *now*. Not by any means small then, it is now, by contrast, singularly large and complete.

On entering the door the whirling sound of machinery in motion apprises us of the fact that we are in a veritable factory. The motive power is placed in the basement, and consists of a Crossley gas engine capable of working up to fifteen h.p. In truth it has a good deal to do, for the large floor immediately overhead is devoted to machines of various kinds which have been called into requisition to aid, or in some cases to supersede, manual labour. The nature and objects of these machines, which seem to us the very perfection of workmanship, may be gathered from the following. To one is assigned the labour—and very short work it makes of it—of reducing the wood to any required thickness by planing, or, more correctly, by means analogous to planing, for it leaves the surface somewhat rough, the real planing or smoothing of the surface being accomplished by another machine standing in contiguity, in which the cutter is in the form of a spiral extending from side to side of the bed plate. This imparts a surface so flat, and at the same time so smooth, as to render it almost ready for the French polisher.

A third machine takes cognisance of moulding and grooving, which when once set ensures all work being absolutely identical, so that any one part made for a camera of a certain size would fit any other camera of like size, and also ensures that all parts finished on it will be exactly similar in pattern and length of moulding, &c.

Machine No. 4 is devoted to recessing, and shaping, and trimming the tops of the shutters of the dark slides. We cannot speak as to the speed at which the others are driven, but incidentally we learned that the cutter in this particular machine runs at the speed of 4500 revolutions per minute.

Of sawing machines there are four, each intended for work of a special class. One of them, of the band-saw fraternity, was employed, when we saw it, in cutting out circles for bases of large studio stands. The others are employed variously for cutting up or grooving. One most remarkable saw which was in use was cutting so cleanly as

to lead one to suppose that the portion of wood severed had just left a plane rather than a saw; the oddest thing being that when the saw was stopped we found it composed of huge shark-like teeth, each about three-quarters of an inch long, instead of fine, small teeth, which one would naturally expect to use for such work. Another, of a peculiar construction, acts seemingly by the sides of the teeth of the circular cutter, and is employed for gauging dark slides, the edges of which it cuts and finishes simultaneously in such a manner as to preclude any further touching.

It seems part of the policy of Mr. Watson to make and put together the various parts comprising a camera, and to keep such parts in a state ready for being in any reasonable quantity placed in the hands of the finishers. In one room we saw thus stored away literally immense numbers of such parts. One recess was loaded with baseboards, another with bodies, another with dark slides or their component parts, and so on, and these in all the various sizes that are made. Two advantages are claimed for this: first, that it enables an order from the sale shop to be quickly executed, from six to twelve being usually taken from this unfinished stock room, and given out to be finished together; and secondly, that thus remaining for some time in a partially finished condition still further conduces to the wood being well seasoned.

Concerning the wood itself, there is a great deal in stock, already sawed up to the approximate thickness and stacked up for seasoning. Mr. Watson does not consider the wood fit for employment in camera making until it has undergone this seasoning process for at least two years.

The various floors are each devoted to some special department. On one of these is the brass shop, where all the brass fittings of cameras are made; here are vices, turning lathes, drilling machines, and a staff of assistants. The lathes, saws, &c., in this shop are all driven by steam power, and the same system with regard to fitting to gauges is applied to the brass work as to the wood work, and the pitch of all the screws are made to Whitworth's standard gauges. The brass work for cameras in its entirety is made here, Messrs. Watson considering that the Midland quality goods are neither sufficiently neat nor solid to match their cabinet work; therefore are made hinges, bolts, side rods, &c., in fact all excepting screws, which Messrs. Nettlefold hold a monopoly for, and which must be obtained from Birmingham. In addition to the small camera brass work, the rack work for heavy studio stands is also prepared here throughout.

There is besides, on the premises, a blacksmith's shop, with forge, where are made the various cutters employed with the machines. To such a degree of excellence have these cutting tools been carried, that one piece of wood which we saw tongued into another piece was such a perfect fit as to lead to the belief that if one could put a piece of glue in his mouth and then breathe upon the junctions, they would not only never separate, but would, when trimmed, defy detection as to existence. The whole of the cutters used for the machines have been made at their own factory and from their own patterns, it having been found that ordinary cutters as used in the trade were totally useless for the special high-class work they were required for, and also for the very hard wood that is used.

At the time of our visit a considerable number of hands seemed to be employed on the new "Acme" camera, which is evidently having a run. Although all the individual parts of this camera are made by machinery as far as machinery is applicable to its production, yet after everything is finished it occupies over two weeks for a highly skilled workman to put together and fit a full-plate one for being placed on the shelves of the warehouse. The thinness, lightness, and rigidity of this camera have caused a run on it which severely taxes the output of the factory, although about one hundred hands are employed in the various wood and brass departments.

We ought also to mention that the upper part of the warehouse, 313, High Holborn, is also used as a manufactory—the top floor for lens grinding, and the next for high-class optical brass work, microscopes, surveying instruments, lens mounts, iris diaphragms, &c. The floors below, consisting of shop and first and second floors, are fitted up as show rooms and offices, and the basement as packing room in the front, and this floor being somewhat extensive, the back is partitioned off and serves as a dark room for demonstrations with optical or enlarging lanterns.

Messrs. Watson & Sons have been extensive contributors to various international exhibitions: being confident in their ability to compete favourably in their specialities with, as they allege, any house in the world, they have not hesitated to compete wherever honour and glory (and recompense) were to be obtained; therefore they have shown successively at Liverpool, Manchester, Antwerp, Brussels, Adelaide, Melbourne, London, and various smaller exhibitions; and

this confidence seems to have been warranted by results, they having received no less than sixteen awards, fourteen of which were the highest given, and the other two were the first obtained by them in earlier days, when the present high class of their work was coming only, and was not, as now, in level working.

CAMERA CLUB CONFERENCE PAPERS. ON THE USE OF DRY PLATES IN PHOTO-MECHANICAL WORK.

By W. T. WILKINSON.

TWELVE months ago, when any one asked me if dry plates could be used for photo-litho and kindred negatives, the answer was that there were no plates in the market to be depended upon giving the absolute clear lines so necessary for success. Now I am glad to say that there are two brands of plates in the market that give negatives quite as good as the wet process when working at its best. This word *best* will, no doubt, recall old memories, the reverse of pleasant, in the minds of many who had to put up with troubles that a dry-plate worker of to-day knows nothing about. Now, in the case of both the operator can get out of it by opening a fresh box of plates; then, no matter how much care was taken, the negatives could not be made.

The two brands of dry plates alluded to above are Mawson & Swan's photo-mechanical, and England's rapid chloride, and upon either plate negatives suitable for photo-litho or photo-zinc—line or grained—may be done equal to the best wet-plate negative, and with infinitely more certainty and far less trouble.

These plates may be developed with either pyrogallie or hydroquinone, the last being perhaps the best. For the sake of those who would like the formulae I use, they are here given:—

Pyro and ammonia:—

STOCK PYROGALLIC ACID SOLUTION.

Meta-bisulphite of potash.....	1 ounce.
Bromide of potash	640 grains.
Water	8 ounces.

Dissolve; then add one ounce of pyrogallie acid; then make up to ten ounces with water.

DEVELOPER No. 1:

Stock pyro, as above.....	2 ounces.
Water	18 "

DEVELOPER No. 2.

Liquor ammonia, -880	1 ounce.
Water	19 ounces.

For a normal exposure use two parts of No. 1 to one part of No. 2.

Pyrogallie acid and soda:—

STOCK SOLUTION PYROGALLIC ACID.

Meta-bisulphite of potash	2 ounces.
Bromide of potash	240 grains.
Water	8 ounces.

Dissolve; then add one ounce of pyrogallie acid, and make up to ten ounces with water.

DEVELOPER No. 1.

Stock pyro, as above	2 ounces.
Water	18 "

DEVELOPER No. 2.

Saturated solution, washing soda.

For a normal exposure use eight parts of No. 1 to one part of No. 2.

Hydroquinone developer:—

SOLUTION No. 1.

Hydroquinone	80 grains.
Meta-bisulphite of potash	120 "
Bromide of potash.....	5 "
Water	20 ounces.

SOLUTION No. 2.

Caustic potash, pure stick	200 grains.
Water	20 "

For a normal exposure use equal parts of No. 1 and No. 2.

Do not waste time and plates trying the ferrous oxalate, as it is the same with these as with ordinary plates; if ferrous oxalate gives a good negative, any of the above developers would have given a better, as under no circumstances will ferrous oxalate give as good a result as either pyro or hydroquinone.

For these plates much more light may be used in the dark room, in fact should be used, so that the whole progress of the development can be seen with comfort. Two thicknesses of golden fabric will be found quite sufficient.

The generally accepted idea for a photo-litho negative is that it must

be dense. Never mind about anything else so long as it is dense. This is wrong. Get as much density as you can without clogging up the lines; but the first consideration is absolutely clear lines. Get this, and the density is of little consequence. Of course, it must be understood that a grey negative will err on the other side.

For making grained screens for half-tone type blocks these plates are a perfect boon, it being so easy to get screens free from stains and spots, a condition of things not always possible with wet plates. Besides, the density required can be obtained at one operation instead of the risk of clogging up entailed by the operation of intensifying with mercury, &c.

A few words as to these screens may be acceptable. For the production of half-tone blocks it is necessary to have a variety of these screens ranging in density from a grey to almost a jet black, the lines in each case being perfectly clear. For each picture to be reproduced a screen must be used that will best suit it. For a flat picture use a thin grey screen, whilst for a hard black-and-white portrait use the dense screen.

The grained negatives resulting from the use of the screen must be developed so as to get the lines clear. Density must not be aimed at, it being neither possible nor desirable.

For collotype work the wet process has no advantages over good dry plates, as with care and skill quite as good negatives of ordinary subjects may be made upon dry plates as upon wet, and that with less trouble and more certainty, whilst for colour-rendering the dry plate gives the best results.

Dry plates can be stripped or reversed with just as much ease and certainty as wet plates.

If the mirror be used for making reversed negatives for collotype, patent plate glass must be used, and this would be too expensive from the necessary failures and other causes, so stripping must be resorted to; and I will here give you the method I have used with unvarying success since 1884. The operations are simple and easy, and its certainty may be judged from the fact that I have never met a brand of plates that it does not suit.

1. Clean a few glass plates a size larger than the negatives to be stripped, soak them in weak acid, rub both sides with a clean rag, and rinse under the tap; then coat with the following solution:—

Gelatine	2 drachms.
Water	20 ounces.
Saturated solution, chrome alum.....	5 drops.

Soak gelatine till soft in the water previously mixed with the chrome alum; then melt and filter the flood over the wet plate and stand up to dry. These plates improve by keeping, so a lot may be prepared at one operation.

2. Clean back and edges of negative to be turned.

3. Place upon a levelling stand, and cover with as much collodion as it will hold without running off.

4. Let this film of collodion set thoroughly right through.

5. Immerse the negative in clean cold water, changing occasionally until the greasy appearance is quite removed and the water flows over the film quite evenly.

6. Immerse the negative in a dish containing fluoric acid, two drachms; water, one hundred ounces. Rock the dish until the corners of film show signs of coming loose; then remove and wash under the tap both front and back.

7. In a dish of clean water put one of the gelatinised plates the gelatine film up. Now place the negative face down upon the surface of water, when by a little careful management the film will leave the glass and float upon the surface of water. Now raise the glass plate gently, carefully adjust the film in position, then lift the two slowly from the dish, and with a soft squeegee carefully expel the water from between the glass plate and the film.

8. Flood with, or immerse in, methylated spirits of wine, then place on a rack to dry.

When it is desired to have six, eight, ten, or twelve negatives upon one plate, they are stripped as above. Then a plate the requisite size, previously gelatinised, is placed on the bench and covered with water, the films being lifted from the water and placed in position one by one; when all are in position place a piece of mackintosh cloth over all, then squeegee well.

The process given here is perfectly safe, and if one or two points are attended to there need be no hesitation in turning the most valuable negative.

The important points are, always clean the back and edges of negative, else the tiny shreds of gelatine usually left on the back of gelatine negatives will be detached by the fluoric acid, and will get between the film and glass when stripped, and being so very attenuated will be difficult to dislodge.

Be sure and get a good film of collodion upon the negative, so that the stripped film is easily handled, and any risk of frilling prevented. Be sure the film of collodion is thoroughly set before immersion in the water, else a portion of the film will be opaque. When this does happen, flood the plate with a mixture of ether and methylated spirits, and remove the collodion by rubbing gently with the fingers, then wash and dry and try again.

Stripping films are not dry plates in the strict sense of the term, but are

close enough allied to come under the heading I have chosen, so I will venture upon a few words as to their use.

In making negatives for collotype printing, the roll holder and stripping films will be very useful, as the negatives after development need only be mounted upon patent plate glass, previously collodionised, and when the paper backing is removed the negative is in its right position for collotype, and if afterwards required for silver or platinum printing can be stripped in the usual way. The Vergara films dried upon collodionised glass are just as useful, as also are Pumphrey's films.

Foreign Notes and News.

M. GATMET has published, under the title of *Procédés Photographiques aux Couleurs d'Anilins*, an interesting description of the various applications of aniline colours, with photography, to decorative purposes. Photographs on glass paper, ivory, mother-o'-pearl, &c., are coloured with these pigments, either the picture itself being in some colour, or else the ground upon which it is printed or transferred to. In the first case the sensitive substance is chromated albumen, in the second asphalt. The book gives descriptions of how to decorate articles the surface of which is not flat, and how to prepare the necessary film negatives; also there is a rather minute description of the aniline-lichtpans process.

A CORRESPONDENT of *L'Amateur Photographe* recently found himself in a little hamlet in Normandy with a dozen negatives to develop, and just as he was about to set to work it struck him that the only available water was extremely calcareous, and that he had only four hundred grammes of ferrous oxalate wherewith to develop. After a little consideration he successfully adopted the following expedient:—He took a litre of the water and brought it to the boil, then, adding fifty grammes of the ferrous oxalate, an insoluble precipitate was obtained and filtered off. The filtrate was again brought to the boil, and twenty-five grammes of ferrous oxalate added. A second time the filtrate was taken, and again a third time, thus some water was obtained which, though not pure, still allowed M. Séguin to develop his negatives.

In the *Wochenblatt* Dr. Stolza indicates the following as the best means of modifying a landscape negative. The following solution is prepared:—

Water	100 parts.
Dextrine	4 "
Sugar	5 "
Bichromate of potassium	3 "

Then a few drops of ammonia are added; the liquid has an ammoniacal smell. This mixture is used to cover the back of the negative. It is then allowed to drain, then the plate is dried in an horizontal position at 60°, and while it is still warm it is placed in a printing frame with the image next the glass, and is exposed to daylight until the film has become insoluble in the shaded parts. A photometer may be used. The plate is then heated again to 60° by artificial light, and very fine powdered graphite is applied with a badger brush. The graphite only adheres to those parts which have not been acted upon by the light. When sufficiently retouched the whole is collodionised and exposed to a strong light, then washed until the yellow tint disappears.

In France, M. Nadar has patented a process for rendering photographic prints permanent. According to the patent specification this process renders all photographs in silver salts—whether upon paper, films, or glass supports—absolutely permanent. It is claimed that it may be used for all photographic prints upon gelatino-bromide of silver, or the corresponding silver salts, and, generally speaking, for all gelatine emulsions, whatever the support may be, provided the pictures are:—1. Normally exposed. 2. Developed with pyrogallie acid or ferrous oxalate, so as to be somewhat more powerful than usual. 3. Washed in water acidulated with acetic acid, and then laid in a bath of the following composition, intended to produce permanency, and which is, in fact, a platinum toning bath:—

Water	1 litre.
Platinum chloride	1 gramme.
Pure nitric acid	20 to 30 cc.

In order to ascertain whether the bath has acted sufficiently a small cutting of a picture treated in the same way is thrown into a ten or twelve per cent. solution of chloride of copper; this should not attack the platinum picture. Thus the hot baths and long exposure of the print required by the platinum process, as it is usually worked, are done away with. Between each of the above operations the print must be thoroughly washed in cold water. The above toning bath may be modified to suit the different sorts of emulsions used. All baths and solutions are used cold, and excellent prints may be obtained by short exposures.

M. LÉFÈVRE is still continuing his experiments in reproductions of spectacular scenes. He has lately taken a series of photographs of the different scenes in *Le Petit Duc*, as played at the Eden Theatre, Paris, which differ from most theatrical photographs by being stereoscopic.

THE CHEMISTRY OF PHOTOGRAPHY.

[A Communication to the Ipswich Photographic Society.]

THE subject our Secretary has induced me to bring forward this evening is one covering a very wide area, and to attempt to investigate the chemical changes involved in every photographic operation which has yet been performed would occupy a very considerable time. I shall merely endeavour, therefore, to explain the part which chemical action plays in the working of photography as most generally practised at the present day. I think you will admit that the gelatino-bromide dry plate is now the article we should be least able to do without in our own photographic work; indeed, it is not unlikely that without the dry plate there would be no Ipswich Photographic Society; this has taken the place of the Daguerreotype, the calotype, and the collodion processes, which, at different periods, have been those generally employed. In the Daguerreotype the sensitive plate was prepared by exposing a silvered tablet to the action of iodine vapour, which combines with metallic silver to form silver iodide—

Subsequently bromine vapour was employed with iodine. By a short exposure in the camera a latent image was produced which appeared when subjected to the vapour of mercury. Hyposulphite of sodium was used as the fixing agent as now, though I believe that at the time Daguerre introduced the process no perfect method of fixation was known.

The calotype or Talbotype process, so called from the name of its inventor, Fox Talbot, seems next to have held the field. It seems likely that paper negatives are once again to become popular, though in the calotype the image was formed in the body of the paper, now it is in the sensitive film on the surface.

This paper was prepared by floating it on a solution of iodide of silver in iodide of potassium, and washing slightly; the paper prepared was of a primrose colour, and would keep for years. Previous to exposure in the camera it was excited by gallic acid and aceto-nitrate of silver being brushed over it, and afterwards developed by the same chemicals.

This process was superseded by the collodion process of Scott Archer, which is still used to a considerable extent. The glass plates, previously coated with collodion (a solution of gun cotton in ether and spirit) mixed with a solution of an iodide (generally cadmium), were sensitised by immersion in a bath of nitrate of silver, thus forming silver iodide—

The latent image produced by exposure in the camera was then developed by pyrogallie acid with either acetic or citric acids, the free nitrate of silver in the film playing an important part in the operation. The negatives were finally fixed by means of cyanide of potassium or hyposulphite of sodium.

I have now come to a matter with which most of us are better acquainted—the gelatino-bromide dry plate, though I dare say but few of us have ever actually prepared one, and their manufacture on a small scale is scarcely to be recommended; their superior sensitiveness and great convenience soon led to the displacement of the collodion process, though this has still some staunch adherents who maintain its superiority; and I believe that for some purposes, as transparencies, it is admitted to be unexcelled. In this, gelatine (the vehicle) is allowed to soak in water in which bromide of ammonium has been dissolved and then the mixture is liquefied by heat; to this a solution of nitrate of silver in distilled water is added gradually, well stirring, and the emulsion, as it is called, is heated for some time (this and subsequent operations must, of course, be performed in a non-actinic light); bromide of silver is thus formed—

Some more gelatine is then added to the emulsion, which is then allowed to set to a jelly; the next operation is to get rid of the ammonium nitrate, which is done by cutting the jelly up into small pieces and allowing the soluble salt to be washed out with water. After being heated and strained the emulsion is now ready for coating plates.

The next point to be considered is, What change occurs on the film by exposure to light on the camera, so that we can eventually obtain a negative by development? We have bromide of silver in a minute state of division, suspended in gelatine. We know that most silver compounds, when in contact with organic matter, become decomposed by light; we have only to place a drop of solution of nitrate of silver on our hands to ascertain this; and other silver salts are much more sensitive. There are several theories as to the composition of the "latent image," and the question can hardly be considered as finally settled.

The solution that is apparently regarded as the correct one in Hardwich and Taylor's *Photographic Chemistry* is that the change is molecular, i.e., that the molecules of silver salts, when acted upon by light, are altered and rendered in such a condition that they are peculiarly susceptible to the action of the developing agent. A molecule, I may say, is, as the atomic theory has it, the theory which is universally accepted by chemists as affording the most rational explanation of the constitution of chemical compounds, the smallest particle of matter which can exist in an uncombined state; a molecule of silver bromide would consist of one atom of silver, represented by the formula (Ag.), and one atom of bromine (Br.).

A molecule must consist of two atoms at the least, and thus we have a molecule of silver represented by Ag_2 ; the symbols, in addition to being shorthand for the name of the element or compound, also represent the combining weight and the volume.

The theory, which till recently has met with general acceptance, and which

Captain Abney favours in his work, is that the silver bromide is reduced by light to sub-bromide (Ag_2Br), the formation of this sub-bromide of course depending on the intensity of the actinic rays of light upon the various parts of the object; this matter is necessarily involved in great obscurity, and no change can be detected by any means in the film before and after exposure, but we know that there is a so-called latent image which becomes perceptible by the action of developing agents; possibly some day we may have a process in which these will be unnecessary, as we may have a direct image formed in the camera.

Another theory having some supporters is that electricity is sufficient to account for the formation of the latent image, but I do not think that the evidence is very strong.

Mr. Carey Lea has recently been investigating what he calls the photo-salts of silver which he has prepared, and which he states are producible from the haloid salts of silver—i.e., the chloride, bromide, and iodide—by the action of light as well as by purely chemical means, his photo-bromide consisting of silver sub-bromide in combination with silver bromide (Ag_2Br , Ag Br), the sub-bromide forming but a small proportion of the whole. This photo-bromide is insoluble in strong nitric acid, whilst the sub-bromide itself is very soluble in it; and as this theory receives strong confirmation in other ways, it appears to be the one most probably correct.

We now come to consider the action of developing agents, which are all powerfully reducing bodies, greedy of oxygen. I take pyrogallol acid first as the developer in general use; this is more correctly termed pyrogallol, as it is not an acid at all, but a phenol, though it is formed by heating gallic acid when it sublimes; its chemical name is trihydroxybenzene, and, like many other names of organic chemical compounds, not remarkable for brevity, though expressing its chemical constitution as a benzene derivative. We have a series thus:—

Benzene, C_6H_6 .

Phenol.

(Monohydroxybenzene, or carboic acid), $\text{C}_6\text{H}_5\text{OH}$.

Paradihydroxybenzene, $\text{C}_6\text{H}_4(\text{OH})_2$.

Pyrogallol (trihydroxybenzene), $\text{C}_6\text{H}_3(\text{OH})_3$.

As I have said, pyrogallol is an energetic absorber of oxygen, and it is used with potash in gas analysis as a means of estimating the quantity of oxygen present.

Pyrogallol is only active in an alkaline medium. Its action on silver sub-bromide with ammonia shows that it reduces the silver to the metallic state, ammonium bromide being formed—

The action of the ammonium bromide which, in addition to pyro and ammonia, is used in this developer appears to consist in diminishing the amount of silver sub-bromide capable of being dissolved by the ammonia. But, if much be employed, the effect produced by light is in a great measure cancelled, owing to the formation of a compound with the sub-bromide, which is as little acted upon by the developer as the bromide itself; hence the amount of bromide admissible is limited.

By using stronger ammonia more silver bromide is dissolved. If amount be in excess of that necessary to supply a gradual aggregation of silver on those parts on which the deposit has already taken place, a veil must result over the whole surface.

By using a stronger pyro solution a more rapid reduction of the bromide will be effected; hence a too strong solution would cause fog.

In place of pyrogallol, a new developer, hydroquinone, or, to give it its proper medical name, paradihydroxybenzene, is meeting with much favour.

Its formula is, $\text{C}_6\text{H}_4(\text{OH})_2$. As will be seen it is a near relative of pyro; in development it becomes oxidised to quinone—

which is a light yellow body, and consequently this developer is free from the unpleasant staining properties of pyro. With hydroquinone ammonia appears unsuitable, and consequently the carbonates or hydrates of the fixed alkalis are used.

Hydroxylamine hydrochlorate ($\text{NH}_2\text{OH HCl}$) has also been used, but during development nitrous oxide gas (N_2O) becomes formed, which is said to cause injury to the film.

The ferrous oxalate developer needs a word. This is a solution of ferrous oxalate in excess of potassic oxalate, ferrous sulphate mixed with potassic oxalate forming ferrous oxalate and potassic sulphate, the former being dissolved by the excess of potassic oxalate present—

This is also a powerful reducing agent, becoming oxidised to ferric salt—

The difference in the state of the iron, before and after development, is readily shown by the action of reagents.

Sulphites of sodium and potassium are often used to preserve pyro in solution, and also to prevent the film becoming stained during development; they appear to act as oxygen absorbers—

though I prefer to use pyro dry, as the presence of sodium sulphate, a great restrainer, can hardly be considered desirable in a developing solution.

The use of alum subsequent to development appears to have a toughening effect on the film, preventing frilling, and tending to remove pyro stain. It is impossible to represent this action by a chemical equation, though gelatine and alum have probably the property of entering into some kind of chemical combination.

In addition to the various reducing agents employed as developers, the alkalis—ammonia, potash, and soda, and their carbonates—are variously used as accelerators; ammonia appearing to act most energetically. When the fixed

alkalies (potash and soda) are used, the films do not appear to be so much stained with the developer as with ammonia.

The next operation is to place the negative in the fixing bath so-called, as it renders the image permanent by removing the silver bromide unacted upon by the light: were this not done, of course the image would be impartially reduced on exposure to light. Hyposulphite of sodium is the fixing agent in general use, though other salts, as potassium cyanide and ammonia, can be used. This salt is properly called thiosulphate, it being considered to be sodium sulphate (Na_2SO_4), in which one oxygen atom has been replaced by sulphur—

This salt acts by double decomposition—

This silver hyposulphite combines with excess hypo, sodium forming the soluble double salt—

There is another double salt formed when the hypo is not in excess—

which is but sparingly soluble; hence it is of great importance that the hypo be not too much economised.

After fixation, a clearing bath of acid and alum is frequently employed, but care should be taken to thoroughly wash off the hypo first or the hypo will be decomposed thus:—

An operation sometimes necessary to perfect or improve a negative is intensification. This is generally done by the application of a soluble mercuric salt (as the chloride) to the film, whereby a deposit of mercury by galvanic action takes place—

The ammonia next applied converts the mercurous chloride into mercurous ammonium chloride.

On the other hand, negatives may be reduced by application of a solution of potassium ferricyanide and hypo; the action taking place here would probably be reduction of the ferricyanide ($\text{K}_3\text{Fe}(\text{Cy})_2$) to ferrocyanide ($\text{K}_4\text{Fe}(\text{Cy})_2$), the oxygen formed, combining with the silver of the image, would as silver oxide (Ag_2O) be removed by the hypo.

Having reviewed the various chemical reactions involved in the production of a negative, I now come to the consideration of positive prints, the end to which the negative is the valuable means. Printing on albumenised paper is probably the method with which the majority of us are best acquainted, and is entitled to first mention.

The ordinary sensitised paper of commerce is paper which has been coated with ammonium chloride and albumen, and then floated on a solution of silver nitrate, so that in addition to the silver chloride formed by reaction between the ammonium chloride and silver nitrate—

silver nitrate shall also be present. This nitrate of silver is responsible for the milkiness noticeable when prints are immersed in water before toning, owing to the chlorides, sulphates, and carbonates present in ordinary water precipitating the respective silver salts.

At the same time when the paper is floated a compound of silver and albumen, termed albuminate of silver, is formed; the albumen has also a mechanical action in keeping the layer of sensitive salts on the surface of the paper.

Albumen is, as we know, white of egg, and as eggs are seemingly more abundant on the Continent than here, the greater part of our albumenised paper is made abroad.

The commercial ready sensitised paper has also, I believe, a small quantity of acid added to improve its keeping qualities.

Chloride of silver on exposure to light, when in contact with organic matter, as albumenised paper, becomes darkened to subchloride—

This liberated chlorine, if nitrate of silver be present, combines with its silver, forming chloride of silver again and free nitric acid.

The albuminate of silver present is reddened by exposure to light to a suboxide (Ag_2O). This suboxide when acted upon by hypo is converted into metallic silver and silver oxide, which is dissolved to a great extent. The hypo also removes the subchloride of silver, leaving a certain amount of metallic silver from it.

Toning consists essentially in the deposition of gold or some other metal upon the silver of the print; before toning it is desirable to get rid of the free nitrate of silver, otherwise nitrate of gold and chloride of silver would be formed by double decomposition. The toning bath generally used consists of a solution of chloride of gold and any salt in which a fixed alkali is combined with a weak acid. Acetates and alkaline carbonates are capable of precipitating gold from a neutral solution in the presence of organic matter. In the acetate bath the following change takes place—

Bicarbonate, phosphate, tungstate, borate, and possibly other salts of sodium or potassium may be used, but the action in all cases is the same, viz., a gilding of the silver particles of the print with a deposit of gold. The varying tones obtained with different salts is no doubt due to the fineness or otherwise of the precipitated gold particles, as well as to the amount precipitated.

In addition to gold, other metals, as uranium and copper, may be used where uranic salts are. Used with gold they become reduced to uranic and

precipitate gold, and are reconverted to uranic; but there are other processes in which uranium itself is deposited on the print.

In fixing prints the chemical change is mainly the same as that in fixing plates viz., by formation of soluble double salts, but other reactions are involved as stated. It will also be noted that from the decomposing action of acids on hypo it is advisable that the alkalinity of the fixing bath be assured; this is, of course, easily ascertained by using litmus paper. The thoroughness of the subsequent washing is also of the utmost importance, as the slightest trace of hypo left in the print is fatal to its permanence, owing to the instability of this salt. A ready test for the determining its absence is to add a little of the so-called iodide of starch, made by adding a solution of iodine to starch paste to some of the washing water, when if any hypo be present the colour will be instantly discharged, owing to formation of iodide and tetrathionate of sodium.

The sulphocyanides of ammonia and potassium are also occasionally used for fixing. Other methods of silver printing are typified by bromide and Alpha paper; in these gelatine is used instead of albumen, and subsequent development is necessary. The bromide paper is, as we should expect from the superior sensitiveness of silver bromide to chloride, as well as to its conjunction with gelatine instead of albumen, much more sensitive to light than that just referred to.

The Alpha paper is gelatino-chloride, and though not so sensitive as bromide is yet much more so than albumen chloride paper. The reactions occurring are of the same nature as described.

Platinum printing is a method having probably a great future before it, owing to its absolute permanence, and is already taking the place of silver to some extent.

The rationale of this process is that the salts of platinum are reduced, i.e., the metal is set free, by ferrous salts, and that ferric salts when exposed to light, under favourable conditions, become reduced to ferrous. The reactions are thus represented—

The ferro-prussiate process is another method of printing from the negative, also much used. This also depends on the sensibility of ferric salts to light. A paper brushed with ferric citrate exposed to light, has its iron, where exposed, reduced to ferrous salt. Now ferricyanide of potassium gives a blue precipitate (Turnbull's blue) with ferrous salts but not with ferric; this reagent is accordingly applied to the print after exposure, and the light-affected parts become proportionately coloured.

I have now another process to consider, one not in general use by amateurs, though our Society has been fortunate in having a practical demonstration brought before it by Mr. Cade. This, the carbon or autotype process, depends upon the sensibility of the bichromates to light. The paper is prepared by coating with a solution of pigmented gelatine; it is then floated on a solution of bichromate of potassium or ammonium. By the action of light in presence of gelatine, these bichromates become reduced, some of their oxygen combining chemically with the gelatine rendering it insoluble—

By the action of hot water the soluble parts, i.e., those unacted upon by light, are removed, and the image remains in pigmented gelatine.

The bichromates are dangerous poisons, and may be absorbed through the skin. I saw it stated in print the other day, that half the employees of the principal carbon works suffered with this disease.

I think I have now touched upon the chemistry of the majority of photographic processes, and if I have not made myself clear in any way I shall be glad to give any further explanation that is in my power. I only hope that I have shown that the photographer who sets to work with an intelligent appreciation of the chemical changes he sets in motion has a considerable advantage over one who views these interesting reactions as merely mechanical and has no other method than "rule of thumb." J. C. WIGGIN.

VEGETABLE DEVELOPERS AND ORGANIC DEVELOPERS.

In *La Science en Famille* M. Mercier, a chemist, writes regarding vegetable developers:—"In the course of recent studies of photographic developers I was led to experiment with a variety of vegetable substances which possess the property of becoming oxidised in contact with the air, under the action of light, gradually assuming a deeper and deeper degree of colourisation. Such are, for example, *ésérine* or *calabarine*, a derivative of the Calabar bean, of which it is the active principle, and which is much used for the treatment of various diseases of the eye. *Esérine*, when pure, has a considerable resemblance to gelatine, absorbs moisture with great facility, and is rapidly transformed into a strongly coloured violet black substance. The solutions keep badly, especially in bottles which are not quite full, and take on there also a deep violet colour. My experiments were made with a solution of one gramme to a hundred, to which was added ten grammes of sulphate of soda and ten grammes of carbonate of potassium. In this solution, which is perhaps rather too dilute, the image develops very slowly, but still it develops, and in from ten to fifteen hours a negative is obtained which, instead of being black like those developed with iron or hydroquinone, is of a beautiful violet colour. In this way positives upon glass may be obtained of a very remarkably delicate shade. If the addition of sulphate of soda be omitted the negative develops

more rapidly, but the solution becomes very rapidly altered. Unfortunately, *ésérine* is expensive, costing no less than ten or twelve francs per gramme; therefore, it need only be mentioned as a photographic curiosity. It is also as a matter of curiosity that I mention certain vegetable infusions which give results that are appreciable, if not very practical, such as the infusion of mullen—flowers. These flowers, when freshly pulled, are of a beautiful yellow colour, but become black when exposed to air and light, and should be stored well heaped together in bottles covered with tinfoil. If an infusion of them be made in water containing five per cent. spirit, and ten per cent. carbonate of potassium, be added to it, and then the infusion be used to treat an exposed gelatino-bromide plate, one will obtain, after a certain number of hours, a negative in which the parts which have been subjected to the action of the luminous rays will stand out visibly. A concentrated infusion of green tea gives sharper results: an image is obtained in which the details are perfectly distinct. One may, for example, take fifty grammes of tea and infuse it in a hundred grammes of water, and, after having squeezed out the infusion and filtered it, one may add fifteen to twenty drops of pure ammonia, after which nothing more remains to be done except to place the exposed plate in the liquid, and to wait a few hours. Chinese ink gives analogous results; in this case it is the tannin which acts, just as in the tea and the mullen. A warm infusion of these substances reduces nitrate of silver, and a cold infusion reduces bromide of silver exposed to light. It is probable that many other vegetable substances, such as fresh walnut water, the juice of which rapidly darkens when exposed to air, would have a similar developing action. *Guaiaicum*, which contains a very easily oxidised resin, produces much more rapid effects. It is sufficient to pour a warm solution of ten grammes of carbonate of soda in a hundred grammes of distilled water upon thirty grammes of *guaiaicum*, which has been previously moistened with alcohol at 90° (but not turned blue by the action of light), in order to have a developing liquid. When an exposed plate is dipped into it the image appears in a few minutes, and a negative is obtained full of details, excessively light, and with a very peculiar yellow tint." With regard to the foregoing and organic developers, M. Eugene Ackermann writes in *La Nature*:—"Having read a recent notice concerning vegetable photographic developers, and thinking it might interest your readers, I wish to point out other two substances which possess the property of becoming gradually oxidised under the action of air and light, and of consequently assuming a deeper and deeper colour. They are *thalline* and *kaïrine*—two substances recently introduced as *materia medica*, and said to be antipyretics. These substances, whether in aqueous or alcoholic solution, when placed in contact with a little paraldehyde, are not long of becoming coloured. This is especially the case with *kaïrine*, which is the subchloride of methyltetra-hydride of oxyquinoleine. The colour assumed by the thalline is a brownish green, gradually becoming brown, while the colour of *kaïrine* is at first red, then a brownish red. It was in the course of certain researches concerning the alkaloids that I had occasion to verify these two reactions, which took place even when the quantities of the substances employed were small. The price of these solutions would be moderate, and one would have the advantage of using solutions of an exact composition, which could hardly be the case with vegetable infusions. With regard to the reaction, I think that the paraldehyde becomes retransformed into the aldehyde for the reduction of both substances."

THE EFFECT OF ELECTRICITY ON DRY PLATES.

[A Communication to the Society of Amateur Photographers of New York.]

I was much interested a short time ago in an account of a demonstration given before an English Society by Mr. F. Greene, wherein he intended to prove that a facsimile of a coin could be impressed upon the moist film of a dry plate by the action of a current of electricity passing between the terminals of a battery, one of which was immersed in an acid solution and the other connected with and rested upon the coin laid on the film of the plate, the latter being also immersed in the solution. After the current passed for a short time, the coin was removed and the plate put into a developer. Soon a distinct negative image of the coin appeared. The experiment showed that by electric action and without the aid of light an impression was made.

Knowing from some experiments made by a friend of mine, Mr. John R. Paddock, of the Stevens Institute, on the electrical conductivity of the bromide film of gelatino-bromide paper, resulting in proving that it was nearly a non-conductor, I hesitated to believe that the result obtained by Mr. Greene was entirely due to direct electric action, but imagined that it might be the result of some secondary effect induced by the electric current. With a view of investigating the subject further, I invited Mr. Paddock to carry on a series of experiments under my direction, and supplied him with a dozen $3\frac{1}{2} \times 4\frac{1}{2}$ gelatino-bromide, and also the same number of gelatino-chloride plates, the latter being of English manufacture. He has recently handed me a report of some of his experiments, which is substantially as follows:—

FIRST SET OF EXPERIMENTS.

A bath of muriatic acid, two drachms; water, ten ounces, was first made. Two gelatino-chloride plates were placed in the bath in a hori-

zontal position, films upward, and on one rested a silver half dollar coin, and on the other a silver dime. The battery consisted of five Leclanche cells, connected in series. The electric current was then passed through the solution for thirty seconds, from the positive platinum pole in the solution to the negative platinum pole on the coin. After keeping the plates in a pyro and potash developer for from ten to twenty minutes the image of the coins was faintly discernible. Plate marked No. 1 shows the result. Merely a faint outline of the coins will be observed.

A third gelatino-chloride plate was immersed in the solution, having the coins resting on the film, but no current was passed through. No impression was obtained on development.

A fourth plate of the same brand was suspended film side downwards, horizontally, in a bath of water. A rubber tube was carried under the solution until the mouth of it was one-fourth of an inch away from the centre of film. Then a current of hydrogen gas was sent through the tube, and in emerging at the mouth gradually spread over the film. When placed in the developer the plate turned a deep black colour over the entire surface.

SECOND SET OF EXPERIMENTS WITH GELATINO-BROMIDE PLATES.

The plates were all immersed in a muriatic acid bath as before, and connected in the same way. On the first plate was placed a half dollar silver coin, having the edges and one face protected with wax. The unprotected face was placed in contact with the dry film, and cemented at the edges with wax, and then immersed in the acid bath, the negative pole being connected to the coin. The current could only act on the under side of the coin next to the film. The current was then passed through for two minutes. In raising the coin from the plate a small portion of the solution worked in under the edge, which appears in the peculiar book appearance shown in the resulting disc; but prior to immersion in the developer nothing was observed on the plate. After development for several minutes a dense black disc, with a faint marking of the dots on the coin, was obtained, but it was nothing like a satisfactory image or facsimile of the coin. In plate No. 2 the peculiarity of the disc will be observed.

Other coins of copper, a German coin (alloy twenty-five per cent. of copper), and an engraved copper plate resting on the film, with the electric current passing as before were tried, but on being placed in the developer no impression appeared.

A third set of experiments included the immersion of chloride plates in a chloride of ammonia bath, using the same electric current and silver coins as above, but the results were not as satisfactory, only indistinct, blackened impressions appearing during development.

A plate was moistened and coins of various kinds pressed down upon the film. On development the impressions came out as good as when no electricity was employed. Plate No. 3 shows the effect very clearly. It should be mentioned that if a chloride or bromide silver film be stripped from a support and be subjected to a current of electricity passing directly through a cross section, the film will blacken at the negative pole by reason of the silver salt in the film.

The opinion of Mr. Paddock and myself is that the blackening effect produced in the film is the result of the reducing action of hydrogen gas, generated in its nascent state, in contact with the film by the current of electricity passing between the two poles, and not to the current alone, as stated by Mr. Greene. This he, in part, proves by causing a stream of hydrogen gas to impinge against the film, immersed in water; when developed the film blackens precisely like the disc obtained with the waxed coin.

Passing next to the effect of a high tension current (such as is obtained by an induction coil) on a dry plate, I have been much interested in an article by J. Brown, "On Figures Produced by Electric Action on Photographic Dry Plates," published in the *London Philosophical Magazine*, and reproduced in the January, 1889, issue of the *American Journal of Photography*. In photographing the discharge between the electrodes of an induction coil, Mr. Brown was led to further experiment on the effect of the current when applied directly to the film. He obtained some interesting results, the most important of which was the discovery that an induced current so slight as to be invisible to the eye produced an impression on the film of sufficient strength to be developed out. He says: "The foregoing results would go to show that actual disruptive discharge over or in the film is not needed to produce an effect visible on development, but that the figures and markings are produced partly, at least, by direct electric action on the sensitive film, without the intervention of a visibly luminous action, or what would be usually understood as a purely photo-chemical cause. Possibly further investigation may show that we have here a new kind of experimental evidence on the relation of electricity to light."

It is presumed the experiments were carried on in absolute darkness, so that the eye might easily detect the least trace of the inductive current. Nothing in regard to this, however, is stated. If a faint red light were used, it might prevent the indistinct electric sparks from being noticed. Plates of extreme sensitiveness were employed, and it is possible they may have been impressed with the faint light not seen by the eye.

A short time ago, with the assistance of Mr. George M. Hopkins, of the *Scientific American*, I tried a few experiments, more especially with a view to determine, first, what the actual electrical resistance of a section

of an undeveloped and developed gelatino-bromide film is; and, secondly, to satisfy myself as to what effect an invisible induced electric current has on a wet and dry surface of a gelatino-bromide film.

First, then, I prepared two sections of plates of exactly the same length and width (four inches long by one inch wide), wrapping tinfoil around each end, and marked respectively A and B. A is the developed and fixed section; B is the plain, undeveloped portion. These in turn were laid upon a block of pure paraffin wax, and then connected with a battery of six standard gravity zinc and copper battery cells, a Bergmann Wheatstone bridge, and a Thompson reflecting galvanometer (the most delicate that is made), and carefully tested as to the amount of current they (the plates) would conduct. After spending nearly two hours in conducting these experiments, the conclusion reached was that there is no conductivity in the gelatine film containing the salts of silver. The only measurement we did obtain amounted to over a million ohms resistance, which is equivalent to infinity. There was no difference either in a developed or plain film.

From an eight by ten gelatino-bromide plate of medium rapidity we cut off four strips, one inch wide and eight inches long. These we respectively laid on a paraffin block and experimented with an induction coil run by five cells of a medium sized bichromate plunging battery. We wrapped the tinfoil about an eighth of an inch in width around the end of each strip, and connected them with the fine wires from the secondary poles of the coil. The by-pass points of the coil were separated about two inches, to force the current to pass over the wires and across the section of the strip. The wires were covered with a piece of silk cloth to prevent any light that might come from them from striking the plate. A very weak induced current was generated and kept up for two minutes. The strip marked C was thus treated. Next a strip marked D, subjected to the same current for the same time, was moistened with water. In each case no current in the darkness of the room was observable to the eye, but when looking closely at the strip the nose detected the peculiar odour of ozone. A third strip, marked E, was then held in the air at right angles to the passage of the spark passing across between the two by-pass points of the induction coil, these being about one and a quarter inches apart. Numerous discharges were allowed to play against it for about a minute, and seemed enough to fog it badly. Lastly, a fourth strip, marked F, was laid on the paraffined cake, the by-pass points drawn apart and the full force of the induced current put on. A bluish light glowed all around it; the current was observed to leap across in the air about half an inch above the strip, showing beyond a doubt that the film had no attraction for it. The distance between the wires connecting it to the strip was decreased one-half; still the current would prefer the air to the plate.

I placed all the four strips (C, D, E, F) in one tray, and poured over them a pyro and potash developer, containing two grains of pyro and four grains of carbonate of potash to the ounce. In about a minute and a half the films of all commenced to turn, and after three minutes' development they were all pretty well blackened.

C and D show no markings other than a general turning of the film. E shows the distinct tracing of the sparks as they flew over the film, the points of contact and departure being very foggy. F shows the effect of the light very plainly at the terminals where it was surrounded by the wires.

In the cases where there was no electric spark visible and where the plate was in total darkness, I cannot account for the turning of the film in the developer, unless it was caused by some subtle influence of the current not fully explainable, or to chemical fog. I at first attributed it to the atmosphere of ozone which must have been over the film, but to prove it I had Mr. Hopkins to generate ozone by running a series of electric sparks between needle points enclosed in a paper cylinder. Rubber tubes passed from each end of the cylinder. At the end of one tube was placed a sensitive plate protected with a metal shield having a star cut in it. After the electric current had generated sufficient ozone in the paper tube, air was blown in one end, which forced the ozone out against the sensitive plate at the end of the other tube. This was kept up for one minute, during which time the ozone was continuously generated. The experiment was carried on in total darkness. The plate marked G was thus treated. After being kept in a pyro and potash developer for ten minutes the entire film simply darkened slightly, but no impression of a star was brought out. The star marks on the edges of the plate developed out very distinctly, as they usually do. From this experiment I am able to conclude that ozone has no effect on a dry plate. Three other plates, marked respectively H, I, J, were next subjected to the induced electric spark by placing them on a cake of paraffin and resting the terminals of copper wire parallel with the edges. Curious discharges of the spark across the plates were easily developed out, showing that a very faint electric light is sufficient to produce an impression. The sensitive plate thus affords a convenient means of recording the varying forms and shapes of electrical discharges.

In order to confirm my conclusion as to the effect of ozone, I supplied Mr. Hopkins with two other plates of one maker, Cramer 40, 4 x 5, and had him expose one in absolute darkness for five minutes to the ozone, and the other for two minutes. These I placed in a hydroquinone developer (ten grains hydroquinone, fifteen grains carbonate of potash to the ounce), and kept them there for half an hour, covering the dish during development. Nothing appeared except a slight darkening of the

film all over; not a sign of the star I had hoped to obtain was visible. Plates marked *K* and *L* were thus treated.

Taking into consideration the excellent electrical conducting qualities of metallic silver, it is rather surprising to note that its salts, when inclosed in a gelatine film, appear to be such a good electrical insulator.

If electricity is ever to be employed in transmitting photographs by telegraph, it will have to be done by some method of controlling the variations of light, and not by any direct action of the current. Mr. Paddock and myself are about to experiment in this direction. The field is an interesting one, and there is room for several useful experiments. What I have said is the latest in this line, and I trust my work may stimulate others to experiment further.

F. C. BACCH.

PHOTO-MICROGRAPHY.

[A Communication to the Glasgow Photographic Society.]

PHOTOGRAPHY has become the handmaid of many arts and sciences, and of none more so than of microscopy, which itself has of late been raised to the rank of a distinct science. The art of photographing the image of a microscopic object, which image has been enlarged by the microscope, is called by the unphonious name of "Photo-micrography," in contradistinction to "Micro-photography," which name has been given by common consent to the art of producing microscopic photographs of large objects, which microscopic photographs require the aid of a microscope to render their details visible. Photo-micrography has probably been practised since photography received its practical application. No one who has used a microscope can have escaped the desire to keep permanent records of the wonders it reveals. Dr. J. W. Draper, of New York, is supposed to have been the first to take a photo-micrograph by the daguerreotype process, as he was also the first to take portraits by this method. Mr. Dancer, of Manchester, produced, about 1840, photographs by the aid of the oxyhydrogen lantern microscope. In 1841 Mr. Richard Hodgson obtained excellent daguerreotypes of microscopic objects, and the Rev. J. B. Reade and the Rev. Charles Kingsley, as well as Mr. Talbot, also devoted their attention to the subject in question at an early stage. Dr. Donné, of Paris, presented, in 1840, to the Academy of Sciences copies of photographs of various microscopic objects on daguerreotype plates, and in 1845, as Moitessier tells us, Dr. Donné "publiait avec Monsieur Léon Foucault un magnifique atlas relatif à l'étude des fluides de l'économie et contenant un grand nombre de figures gravées d'après des images daguerriennes."

In this country one of the earliest publications on the subject of photo-micrography was a paper presented to the Microscopical Society in 1852 by Mr. Joseph Delvee, which was followed by some beautiful prints taken from his collodion negatives, which were issued with the following number of the *Quarterly Journal of Microscopical Science*. The short time at my disposal this evening does not permit me to enter further into the history of my subject, and I will confine myself to mention the names of some of the principal workers in the domain of photo-micrography. These are Messrs. Shadbolt, Hignley, F. H. Wenham, Dr. Maddox, the inventor of the gelatino-bromide dry plates, Barry, Davies, Dr. Wilson, Dr. Abercrombie, Dr. Herapath, George E. Davis, Dr. E. M. Crookshanks, J. Mayall, jun., E. M. Nelson, and many others. In France we have, besides Donné and Moitessier already mentioned, Foucault, Dubosq, Dr. Miguel, Bertsch, Roux, the assistant of Pasteur, &c.; in Germany, Gerlach, Albert, Mayer, Reihardt, Pohl, Siebert, Dr. Koch, Dr. Roderich Zeiss, Professor Cohen, Reinseh, and many biologists and physiologists of the present day; in Belgium, Neyt, and, in recent times, Dr. van Heurck, Director of the Botanic Gardens in Antwerp; in Italy, the Abbé Count Castracane; and last, but not least, in the United States of America, Rood, Draper, Fowler, Crehore, Dean Rutherford, Seiler, Mercer, Dr. Sternberg, Dr. Colonel Woodward, and Dr. Curties, of whom the latter stand pre-eminent as masters of photo-micrography. The number of those practising this art to-day has probably to be counted by thousands.

The object of photo-micrography is to produce a faithful photograph of the enlarged image of a microscopic object, which shall not only show everything apart from colour what we can see in the microscope, but even more. The microscopical image can also be drawn by means of a camera lucida, but this process requires a great deal of time and a hand skilled in the use of the pencil. Frequently, however, we are unable to delineate the image in this way, owing to rapid changes in the constitution and the shape of the object under observation. A drawing is, moreover, always open to the objection that the draughtsman may not have copied faithfully, and may have drawn upon his imagination. From this reason retouching is not permissible in photo-micrography. The negative must remain untouched; intensification or reduction of density are the only changes which, in some circumstances, may be made in the negative. The importance of photo-micrography is obvious, as it is the most reliable and easy means of making faithful records of the appearances and measurements of microscopic objects, be it for the illustration of scientific books or for lantern slides to illustrate lectures, or for supplying evidence in law courts in cases of adulteration, forgery, murder, &c. In the domains of botany, biology, physiology, pathology, bacteriology, chemistry, petrology, &c., in fact, wherever the microscope is used, there photo-micrography is destined to become daily of more service and im-

portance. It is also an agreeable and useful pastime to the possessor of a microscope and of a camera, and can be practised independently of the weather and of the light of day, for even at night plates may be exposed and wasted to satisfy the most enthusiastic amateur. As a means of practising the virtues of patience and perseverance, photo-micrography is, in my humble opinion, almost unsurpassed, for endless are the failures and troubles which the beginner in this branch of our black art will have to encounter. There are the difficulties of finding suitable objects; of their correct illumination; of suitable objectives; of equal illumination of the plate; of obtaining the correct chemical focus; of correct exposures, varying from a fraction of a second to several hours; the chances of vibrations during exposures over which the photo-micrographer has no control; the difficulties of development and of printing, and so on. Owing, however, to many important improvements in microscopical lenses and apparatus, as well as to the greater perfection and sensitiveness of the dry plates, and thanks, also, to the experience of those who have practised photo-micrography for years, and of whose experience the younger disciples are reaping the benefit, photo-micrography is now very much easier than it was even five years ago, and, indeed, it may be said that when practised with low and medium powers offers few difficulties, if any.

The *modus operandi* of taking a photo-micrograph consists chiefly in the following operations:—

1. Focussing and illuminating the object in much the same way as for visual examination.
2. Connecting the eyepiece end of the microscope with the camera.
3. Focussing the image on the focussing screen.
4. Replacing the latter by the carrier containing the sensitive plate, and making the exposure.
5. Developing the negative.

Many articles on photo-micrography have appeared, chiefly in photographic publications, which really do not contain more information on the subject than what I have just enumerated. In the February number of a quasi-scientific journal appeared again one of those shallow articles, in which the writer of it stated that he was greatly pleased and astonished that he had succeeded in producing at once some passable photo-micrographs.

To command success in photo-micrography requires not only the possession of a good microscopical apparatus and camera, but also an intimate acquaintance with the principles of microscopical illumination and of photography.

Regarding the necessary apparatus, the *microscope stand* claims first our attention. It need not be large and complicated, but it must be good; above all, it must be steady and free of tremour, as all vibrations imparted to the stand supporting the object will make themselves the more felt the more the object is magnified, and will result in a blurred image. The stand must possess a good and extra sensitive fine focussing adjustment, which keeps the objective strictly in the optical axis of the instrument, and does not move the image about in an eccentric fashion on the focussing screen. As regards the general plan on which an instrument for photo-micrography should be built, I consider it most desirable that it should be built on the old Ross or crane-arm model as far as the support of its body or optical tube is concerned, because you can then replace the ordinary single or the binocular body by a short or a long body tube of about two inches in diameter, which prevents the projection of a luminous flare spot in the middle of the light sensitive plate, and which flare spot is caused by the internal reflection of the narrow body tube, and is generally not much noticeable on the screen. All microscopes are provided with one or two mirrors; in the latter case, one is plane the other concave, but in photography it is generally preferable to use the light direct. A diaphragm, i.e., a plate pierced with a series of holes of different sizes, or an iris diaphragm, is an indispensable adjunct of a microscope, as it enables us in many cases to give sharpness or depth to the image by stopping down the angle of the illuminating cone of light, provided always that in doing so we do not sacrifice the amount of resolving power requisite for the display of the structure of the microscopic object.

The mechanical and concentric rotating stage is a luxury if it is of the best possible workmanship, but an inferior mechanical stage is an abomination to which a substantial plain stage is infinitely to be preferred. In order to display successfully the delicate structures of microscopical objects, we must have recourse to all the refinements of illumination which we can command, and we must bear in mind that the intensity of the illumination of the image projected on the focussing screen decreases in inverse ratio with the superficial magnification of the object. Thus, if we magnify an object 1000 diameters, or one million times superficially, the intensity of the illumination of the image on the focussing screen or on the sensitive plate is only the one-millionth part of the intensity of the illumination of the object itself, and from this we have further to deduct the losses which the light suffers through absorption and reflection in passing through the lenses of the microscope. In order to increase the intensity of the illumination of the object, we require to make use of various appliances which serve for the concentration of a greater quantity of light on it than what it would receive without these appliances, and which are termed condensers and reflectors. The simplest condenser is the stand or bull's-eye condenser; generally a plano-convex lens of large diameter, and sometimes a Herschellian condenser, which is composed of two such lenses, and which arrangement is capable of giving a larger and flatter illuminated field than the single lens. The stand condenser is an indispensable and most useful piece of apparatus, and if properly under-

stood can be turned to excellent account. By its means we are enabled either to fill out the aperture of a low-power objective with light, or to focus an intense bright and sharp image of the source of light on the object, which is one of the axioms of microscopical illumination under medium and high powers. For these latter, achromatic substage condensers are required which project an illuminating cone of great angular aperture on the object. They consist generally of two or three plano-convex superimposed lenses, and one or two diaphragm discs, the one containing a number of apertures, sometimes from the $\frac{1}{16}$ th of an inch in diameter, as in Powell and Lealand's condenser, to the full size of the anterior lens. The second diaphragm contains various central spots to produce dark-ground illumination, and a number of single or double slots, so as to give only marginal or oblique light from one or two directions. Some of these condensers, such as Abbé's, as well as certain specially constructed condensers for the use of immersion objectives, the nature of which I shall explain later on, require to be united with the under side of the object carrier or slide by means of a drop of fluid of far higher refractive power than air, such as water, glycerine, fennel oil, cedar-wood oil, &c.

Apart from these achromatic condensers, we have diffusion condensers for low powers and dark-ground condensers—such as the spot lens, the dry and immersion paraboloids, Wenham's reflex illuminator, &c., which make transparent objects mounted on transparent ground appear brilliantly illuminated by reflected light, leaving the ground quite black. The principle of dark-ground illumination is to send the light rays so obliquely on the object that in passing through it they do not enter the front lens of the objective, but pass on beyond it. In this way only rays which are reflected from the irregular surface of the object itself reach the objective, all axial illuminating pencils being stopped off.

Correct microscopical illumination depends, first of all, upon the choice of the illuminator, and, secondly, upon its proper adjustment and focus, and, also, upon the relation of the aperture of condenser to that of the objective, the rule being that the aperture of the condenser ought to be the same as that of the objective, if we wish to obtain critical images.

The micro-polariscope is an accessory which serves to illuminate objects by polarised light, and is especially useful for differentiating the structure of certain classes of microscopical objects. It consists in its usual form of two prisms of Iceland spar, of which the larger one is called the polariser. The polariser is always placed below the object to be examined, whilst the smaller prism, termed the analyser, is placed above the object, either between the objective and the body of the microscope or above the eyepiece. In the latter position of the analyser, the definition is better than in the former, but it cuts off two segments of the field of view. Both polariser and analyser must be capable of rotation round the optic axis of the instrument.

Opaque objects may be illuminated by the bull's-eye condenser, by prisms, or by reflectors, which are generally made of so-called speculum metal. Such reflectors are the parabolic side reflector, the cylindrical reflector, and the Lieberkuhn. This latter is an appliance resembling in shape the mouthpiece of a trumpet; its parabolic surface is silvered and it slides over the objective, the focus of its parabolic surface coinciding with that of the objective and the position of the object on the stage. The Lieberkuhn has to be illuminated by rays parallel to the optical axis, and the objects for it must be mounted, so that the light from the mirror can pass around them and fall on the silvered parabolic surface, from which it is reflected downwards on the object.

The compound microscope consists of objective and ocular or eyepiece, and the former is by far the most important and essential part of the instrument. Micro-objectives are achromatic combinations of lenses, because it is impossible to produce single lenses free from chromatic and spherical aberrations, which defects make themselves most felt in lenses of great apertures. Micro-objectives are designated by their focal lengths, expressed in inches and fractions of inches, or in millimeters; thus we speak of lenses of 4, 3, 2, 1, $\frac{1}{2}$, $\frac{1}{3}$, $\frac{1}{4}$, $\frac{1}{5}$, $\frac{1}{6}$, &c., and $\frac{1}{10}$ inch focus, but these foci do not represent the actual foci or working distances, which are far shorter, but they represent the focal lengths of single lenses having the same magnifications as these compound systems—in other words, these figures represent the equivalent focal lengths of single lenses. A micro-objective possesses certain qualities in a greater or less degree. There is, first of all, the defining power or definition, by which is meant the completeness of its corrections for spherical and chromatic aberration, which quality is easiest attained in lenses of moderate aperture. The flatness of the field of an objective enables us to see the central and the peripheral portions of the field simultaneously equally well defined. The penetration or penetrating power, which is called depth of focus in photographic lenses, enables us to see parts of an object lying in different planes well defined, and this without alteration of the focus. The penetrating power of a micro-objective is very limited, and becomes the more so the wider the angle, and consequently the greater the resolving power. This want of penetrating power is the weak point of a photo-micrograph, because only one plane of the object is in focus. The penetrating power decreases in inverse ratio with the aperture of a lens. One of the most valuable properties of a lens is the resolving power, by which closely approximated structural details and surface markings, such as lines, gratings, dots, and apertures are separately discerned or optically resolved. The resolving power, proper corrections of the lens granted, depends upon the angular aperture of the objective, or upon its capacity of collecting oblique image-forming rays proceeding from the object, provided always

that these rays pass through the object glass and assist in forming the image. Hence opticians strive to make micro-objectives with as wide apertures as possible, the largest in air being obviously 180°. Not content with this, they are supplying immersion objectives, whose front lenses have to be immersed in a drop of water, glycerine, or oil placed on the thin glass covering the object.

PATENTS COMPLETED.

A PORTABLE TRIPOD STAND AND HEAD.

No. 9518. WILLIAM MAVITT, Unity-cottage, Heathfield-road, Birchfield, Birmingham.—*June 30, 1888.*

THE stand is composed of three portions, one part folding with nick and spring joint, and the other sliding, the combination when closed being perfectly square and solid, and practically indestructible by ordinary fair usage—the material to be either of wood, metal, or other substance, or combinations thereof—and the dimensions immaterial.

The head is different in form from most other arrangements of the kind, the legs being connected inside the ears of the head, instead of outside, and the traversing set screw or pin and bolt render the attachment so rigid and perfect that only by a breakage can the legs become detached.

IMPROVEMENTS IN APPARATUS FOR PRODUCING AND DISCHARGING CURRENTS FOR WASHING PHOTOGRAPHIC PLATES AND PRINTS OR OTHER ANALOGOUS PURPOSES, CAPABLE OF BEING ATTACHED FOR USE UPON OR TO ANY ORDINARY VESSEL.

No. 9711. WILLIAM TYLER, 57, High-street, Aston, Birmingham.—*July 4, 1888.*

THIS invention relates to apparatus used for washing photographic plates and prints, or other similar purposes, and the object of my improvements is the construction and arrangement of such apparatus to agitate and cause the water to flow in several differently directed currents, so as to thoroughly wash the said plates or prints, &c., and also for the discharge of the overflow or impregnated liquid, by means of a pipe which is made to work automatically, or otherwise, at the will of the operator; and, further, so constructed and arranged that it may be readily attached to, or carried upon, any ordinary tank or vessel.

I provide what may be generally termed an inverted U-shaped hollow box, or syphon-like pipe, which permits of its being readily hung or carried upon the side of, say, a bucket, or other vessel; that part of the said pipe overhanging the outside of the bucket, &c., being the discharge part or pipe.

At the upper end of the discharge pipe the box is divided off into two separate compartments; the compartment of the discharge pipe continuing on again further, downwards to the other end of the box, lying within the vessel, which said end may be open or covered with a perforated plate, or such other perforations as may be desired may be made in such pipe near the end; thus, there is a continuous but independent passage from the one end in the vessel to the other end outside the vessel forming a syphon.

Again, at the crown, or upper part of the box, an opening is formed into the second division or compartment, which said opening is provided upon its exterior with a nozzle or its equivalent, whereby it may be connected to a water main or other supply. This supply would enter and pass with more or less pressure. This second compartment is then continued on as far as the inner end, or thereabouts, of the syphon pipe, and its end closed or blocked up, or, if preferred, it may be formed of a separate pipe, connected to the syphon pipe at its crown or upper bent part.

Near the lower end of this second pipe, which I will term the current producer, and in its interior, I provide short angular outlet pipes or tubes; three of such outlet tubes I find to answer well, but I may add more or put less. These said tubes are placed at various desired angles to each other, so that as the water, &c., passes through them into the vessel it shall issue therefrom in differently directed streams, thereby producing considerable agitation or whirling in the water in the vessel, in order to thoroughly wash the plates or prints, &c., placed therein. Upon the exterior of the current-producing pipe, and in suitable proximity to the outlet openings of the angular tubes, ballie plates may be used so as to still further direct the issuing streams.

Again, at the upper part or crown of the syphon pipe a communication is made from the supply chamber thereto, so that when such communication is open the water may also pass down the outer portion of the said syphon pipe; provision, however, is made so that at will such communication may be cut off by means of a valve or its equivalent operated from the exterior. Thus, when the apparatus as already described is in action and the valve open, the passing of the water down the discharge pipe exhausts the air from the whole of its.

length, and consequently produces the syphon action, when the valve may be closed and the syphon action would automatically continue, discharging the surplus water, &c., from the vessel or tank.

By these arrangements an apparatus is made which is simple, effectual, and convenient, as it may be applied to any ordinary vessel or tank.

IMPROVEMENTS RELATING TO THE MOUNTING OF PHOTOGRAPHS, AND TO THE PREPARATION OF FAC-SIMILES OF PUBLIC AND PRIVATE RECORDS, DEEDS, AND THE LIKE.

No. 5173. DANIEL KINDLE ZUMWALT, Visalia, Tulare, California, U.S.A.—
March 26, 1889.

My invention relates to an improved method of mounting photographic proofs or prints in such manner as to neutralise the tendency of the sheets to cockle or curl up, which in connexion with other steps of my said invention, as hereinafter fully explained, is particularly adapted to the production of fac-simile copies of public records, deeds, and legal instruments of record in a form suitable for convenient handling and reference, and as a substitute for and an improvement upon the mode or method of copying such papers and instruments by hand, as heretofore generally done in public offices.

The objects sought to be attained in and by my invention are to reduce the size and bulk of record books, to give fac-simile copies of all papers and instruments, whether written or printed, with every erasure, interlineation, peculiarity of handwriting, and every characteristic of the original, to prevent fraudulent alterations in such records, and to greatly reduce the cost of preparing the same.

To attain the ends of my said invention I mount the photographic proofs or prints of the papers or instruments previously taken in the usual way by means of a camera, and place and fix the sheets in pairs back to back without any intervening card or sheet, so that the tendency of the sheets to cockle or curl up is neutralised, and the prints preserve a flat condition at all times.

By photographing deeds, mortgages, and like instruments of record, and then mounting the prints back to back in the manner named, and binding or uniting the mounted sheets in book form, with the pages properly following one another, I prepare and produce reduced fac-simile copies of such papers, which are exact in every respect.

In the case of a deed or other instrument presented for record, instead of being copied by hand into a record book, as heretofore, I now take a photograph of it, and from the negative obtained I print copies in the usual way upon albumenised paper. A print is obtained in this way of each page of the instrument, and then every two prints or copies are firmly pasted together back to back to produce a single leaf or sheet. As many leaves or sheets are formed in this manner as it requires to produce all the pages or sides of the instrument, and all the copies thus prepared of instruments filed for record from time to time are made of uniform size, and are bound together in book form to produce a volume of convenient size.

By mounting two sheets of the albumenised paper back to back in such manner I am enabled to dispense with cardboard or paper mounts, because the tendency to cockle or curl is entirely overcome, and the sheets will lie flat and smooth when the book is opened. In consequence of this it is practicable to bind a considerable number of these leaves or sheets together. A volume of these photographic copies will be more compact and of less bulk than a manuscript volume of the same matter.

This method of producing and forming fac-simile copies of public records is particularly applicable to the preparation of abstracts of title in a complete form. In such case of application of my said invention copies of the deeds and other instruments in the chain of record are prepared as before described, and the photographic copies thus obtained are mounted, as before mentioned, and then bound together in the order of their dates. An abstract thus produced will present a reduced fac-simile copy of every deed, transfer, mortgage, and other instrument affecting the title in question, and will be produced at much less expense in many cases than could be done by hand.

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I declare that what I claim is:—1. The within-described improvement in the art of mounting photographic proofs or prints, consisting in mounting such proofs or prints back to back in the manner set forth, whereby the tendency of the sheets to cockle or curl inward toward the albumenised or printed side is neutralised, as set forth. 2. The herein-described improvement in producing and preserving fac-simile copies of deeds, records, and other legal documents and instruments, which consists in first obtaining a photographic print of each page of the document to be recorded, then mounting every two sheets back to back, and finally arranging and binding such leaves or sheets in proper order into book form.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

MAY 16.—Mr. Elgar Clifton in the chair.

Mr. P. EVERETT reported that he had tried comparative experiments to test a statement in a photographic journal that acetate of soda would do in place of

a carbonate or an alkali in development, the result being that he found that acetate of soda would not act at all.

A question in the box asked how gold could be prevented depositing itself in the bottle containing the toning solution.

Mr. A. MACKIE said that if the toning bath had not a tendency to deposit gold it would not tone at all; the deposition could be prevented by making the solution in the bottle slightly acid and making it slightly alkaline again whenever required to be used for toning purposes.

Mr. W. ENGLAND asked the cause of some spots on a negative on one of Carbutt's films which he produced.

The CHAIRMAN thought that the glycerine in the film to keep it flexible might perhaps cause the spots by dampness; the pictures produced on the rapid Carbutt films were wonderfully free from halation, but the film must not be supported in the dark slide by a plate of glass; the latter would give great halation because of its reflecting surfaces.

Mr. A. HADDON remarked that there was plenty of camphor in the Carbutt film; scraping the film with a knife brought out the smell.

Mr. A. COWAN thought from the look of the celluloid film that it had been roughened by the sand blast before coating.

Mr. F. P. CENBRANO thought the roughened surface to be made to hide the fine lines which on close examination could be seen crossing the film.

The CHAIRMAN supposed that the films might be shaved from large blocks, and that the fine lines might be caused by the blade of the cutting instrument.

Some slides by Messrs. Everett, England, Atkinson, and Freshwater, were then exhibited by the aid of the lantern.

NORTH MIDDLESEX PHOTOGRAPHIC CLUB.

MAY 20.—Mr. Hiscock in the chair.

Negatives were exhibited by Mr. Walker, and slides by Mr. Davall.

On the question being raised as to the best means of preventing halation, Mr. HAYMAN said that Messrs. Samuel Fry & Co. had introduced a plate ground on the back which almost entirely overcame that difficulty.

A print was passed round of the interior of a room facing a window, one-half of the window being on plain and the other on ground glass, and taken by an amateur; that on the ground side being entirely free from any trace of halation. Another means of obtaining the same end was to use celluloid films.

One of Blair's whole-plate cameras was also shown by Mr. Hayman, weighing only five and a half pounds, and yet including every motion necessary to a good camera. A half-plate camera and three slides complete weighed about five pounds, the slides weighing three ounces each. He then exhibited a novelty in the way of a frame for transparency and lantern slides, which it was their intention to bring out in the coming season. It was a small nickel-plate metal frame, which was adjustable by means of a metal rod which formed the side, and passed through a small ball at the top and bottom corners, and was grasped in position by a screw at the back.

It was suggested by Mr. BRADLE that if the sides were made the same as the top, so as to grasp it all the way round (which could easily be done by a slot in the ball), it would be a decided advantage.

The first outing of the members and friends will take place on Saturday next, May 25, to Totteridge, working to Mill Hill. Train from Finsbury Park, at a quarter to three. Visitors invited.

HOLBORN CAMERA CLUB.

MAY 17.—Mr. F. W. EDWARDS gave a demonstration in the Club Room on *Platinotype*, developing some four dozen prints, many of them being 20 x 12.

MAY 18.—A party of twelve visited Waltham Cross and secured some very pretty views of the Abbey and other places of interest. There were four ladies in the party, three being members of the Club.

On Friday next there will be a lantern display in the Club Room; all who like may attend.

UNIVERSITY COLLEGE PHOTOGRAPHIC SOCIETY.

MAY 18.—Abstract of paper on *The Applications of Photography to Book Illustration*, by Mr. W. North, M.A., Hon. Secretary.

The object of the paper was to set out the principles on which the various photo-mechanical processes depend, without discussing technical details. In this way all direct methods for the production of prints from individual negatives were excluded from consideration. Light has an action upon ordinary paper which, though well known, does not attract quite so much attention as it deserves. This action is really upon the size, and though perhaps not understood is appreciated by painters in water colour, who have learned by experience that an old paper is safer for their purposes than one but recently made. The reason is not far to seek; in a new paper the process of oxidation of the size involves the colours used upon it, and they suffer accordingly, whilst in an old paper the process is complete, and any action which may take place is on the colours alone. This action can be made more manifest by treating the paper with certain salts, and especially potassium bichromate. In this case, according to the authorities, one molecule of chromic oxide and two molecules of potassic hydrate are produced, the result being a visible image of a dirty orange colour. But not only is there a visible image; the film of bichromated gelatine has its physical qualities altered in such a way that the parts which have been exposed to light become insoluble in water, and refuse to absorb it. Nor is this all; the result of wetting such an exposed film is to produce an image in relief from which a cast can be taken in plaster. And, moreover, if the film be inked with a printer's roller, it will be found that the ink will only adhere in those parts which have been acted upon by the light. [Films were shown, and the effect of wetting in producing an image in relief was demonstrated. A collotype plate kindly lent by the manager of the Automatic Engraving Company was then inked, the process of collotype printing briefly described, and a number of specimens of work handed round. A mould in high relief and a cast from it were also shown.] The method of preparing lithographic transfers from line negatives was then

described, and examples of photo-lithography passed round. Next the Woodbury process was described and illustrated by gelatine reliefs, metal moulds made from them by hydraulic pressure, and a quantity of Woodbury prints in various styles kindly lent by the Company for the purpose. The method of producing zinc blocks by means of the action of light on bitumen was then described, and illustrated by the actual development of exposed plates. Examples of blocks and prints of various kinds from zincs lent by Messrs. Paterson & Co. were handed round. The use of grained negatives and the processes for the production of printing blocks in half tone were briefly described, and the paper concluded by some general remarks as to the progress made in book illustration by photo-mechanical processes.

Mr. Davis then exhibited some exceedingly beautiful examples of the Fretsch process, the general principles of which he shortly described, and after a lengthy discussion and the answering of a number of questions by the author of the paper, the meeting was brought to a close by a vote of thanks to the author and to the various firms who had so much contributed to the interest of the meeting by the loan of material for the illustration of the paper.

The next meeting will take place on Tuesday, May 28, when a paper will be read by Mr. J. T. Leon on *Direct Printing Processes*.

The Society held its first field excursion on Saturday, May 18, when a number of the members went to Pinner. It is hoped that a large number of the negatives taken will be on view at the next meeting, and that members will avail themselves of the opportunity of comparing results.

SHEFFIELD PHOTOGRAPHIC SOCIETY.

MAY 7.—Mr. B. J. Taylor in the chair.

It was announced that arrangements had been made with a local artist to criticise, from an artistic standpoint, the work of members monthly, with a view to raising the standard of the art side of photography.

A demonstration was given by Mr. J. W. CHARLESWORTH on *Platinotype Printing (Hot Bath Process)*. This process is rapidly coming into public favour, and the ease with which the prints can be produced was ably shown by Mr. Charlesworth.

Several members expressed their intention of taking up the process.

Arrangements have been made for an excursion to Haddon Hall on Thursday, May 30.

On Tuesday, May 14, the slides sent to England by the Boston Camera Club, U.S.A., were exhibited, and were much admired, the lecture which accompanied the slides adding greatly to the enjoyment of the evening. A number of slides of New York were also shown.

BRADFORD PHOTOGRAPHIC SOCIETY.

RELATIVE to the judging of pictures at the Society's exhibition, it was proposed that the members of the Manchester Photographic Society be asked to appoint two of their members to act as judges.

Mr. WALTER LEACH, F.C.S. (Secretary to the Society), then gave a short lecture on *Photographic Lenses*, dealing first with the single lens, and explaining the cause of distortion and chromatic aberration. The construction of achromatic lenses to do away with the latter difficulty was then explained. Compound lenses, such as landscape, rapid rectilinear, wide-angle, &c., were also illustrated, and the proper use of each class of lens indicated. The diaphragms or stops were then alluded to, and their utility in forming the most suitable effect in a picture explained. A simple way of calculating the relative value of the stops, so that exposures could be more easily calculated, was then explained, and attention drawn to the fact of very few photographers knowing or understanding the value of a large or small stop, as they are generally called.

Two new members were proposed and elected.

Correspondence.

Correspondents should never write on both sides of the paper.

THE PLATINOTYPE PROCESS.

To the Editor.

SIR,—In a paper recently read by Mr. W. Lang, jun., that gentleman makes a statement which we think we are justified in assuming infers that the patents connected with our process are no longer in force, for he is made to say, "Being protected by patent, although this no longer applies, for all are now free to use it." Mr. Lang may have intended a different meaning to be conveyed from what we consider to be the natural interpretation of the words. We will ask you to permit us to state that the patents still "apply," and that only those who use our manufactures are "now free to use" the process. In fact, the only practical difference now from former times is that we do not require a fee of five shillings to be paid by licencees in the ordinary way.—We are, yours, &c.,

THE PLATINOTYPE COMPANY.

29, Southampton-row, High Holborn, W.C., May 24, 1889.

PHOTOGRAPHING IN NORWAY.

To the Editor.

SIR,—Your correspondent, F. Coop, is not very definite in his requirements about Norway. As to exposure, it is about the same as in England. Thus, in exposing for the Old Stavkirke at Borgund at 3.15 p.m., *f*-61, exposure was three seconds on Ilford (yellow) extra rapid plate; exposure for North Cape at midnight was for same aperture twenty-five seconds

With the same plates and *f*-16 I got a good many views with one-sixteenth of a second by hand from deck of steamer. Your correspondent does not say whether he is yachting or not, nor the time he has at his disposal, so one is unable to advise him much. I should say, get Cammermeyer's Reise Kart (travelling map) for North and South Norway (five sheets), and mount on linen as pocket maps. As to objects to photograph, he will find them every few yards on land. If he only sticks to the ship I think the Lofoten scenery the grandest. If only for a short visit I would recommend the Hardanger Fjord. I would not go up to the North Cape, unless to be able to say I had done it. Nor would I go above Tromsø. I shall be glad to answer any question upon any part of the coast I know.—I am, yours, &c.,

West Lodge, Galway, May 17, 1889.

R. O'H.

THE METRIC SYSTEM.

To the Editor.

SIR,—I have the pleasure herewith to submit to you the Report of the Sub-Committee of the Photographic Club on Weights and Measures, and to ask your co-operation in getting the Metric Decimal System adopted, especially by those photographers with whom you are associated.

The confusion arising from the methods of weighing and measuring at present in use makes the accurate translation of formulæ impossible; for example, the term ounce is represented by two distinct weights, the Troy ounce being 480 grains, and the Avoirdupois ounce 437½ grains, or that by which chemicals are usually sold; the term ounce being used indiscriminately in writing formulæ. The Photographic Club, in making this attempt to secure uniformity in weighing and measuring, trust that the accuracy that will be secured by the general adoption of the Decimal System in writing and translating formulæ will be sufficient to overbalance any little inconvenience that may be incurred in the early stages of its use.—I am, yours, &c.,

EDWARD DUNMORE, Hon. Secretary of the Photographic Club,
Arderton's Hotel, Fleet-street, May, 1889.

REPORT OF THE SUB-COMMITTEE ON WEIGHTS AND MEASURES.

WE, the Sub-Committee appointed by the Photographic Club to consider the desirability of adopting a uniform system of Weights and Measures, having fully discussed the matter in all its bearings, have come to the unanimous decision to recommend the adoption of the Metric Decimal System, pure and simple.

The demerits of the present British System require but little consideration to condemn it. The absence of any definite unit or integral subdivisions, and the different values attaching to the denominations, lead to vagueness and error, while the difficulty of making calculations and of translating foreign formulæ is a constant source of trouble, and no modification of the present system has come before us which is free from these faults.

On the other hand, a very little experience of the Metric System proves its simplicity, and the fact that it is universally adopted in scientific literature and practice, and that it has always been in actual use on the Continent for photographic purposes, points to it as the only alternative to our own defective system. It may be mentioned that the cost of the decimal weights and measures does not exceed that of those now in use.

It is hoped that the Photographic Club, in adopting this system, will have the support of all the metropolitan and provincial societies of the United Kingdom, and if at the same time the representatives of photographic literature, and plate makers generally, some of whom have already signified their acquiescence, can also be prevailed upon to lead their aid, it would, perhaps, more than anything else tend to the universal employment of the Metric System amongst authors and users of photographic formulæ.

Signed on behalf of the Sub-Committee,

May 8, 1889.

W. ACKLAND, Chairman.

Exchange Column.

Will exchange electric bell and fittings for backgrounds, posing chair, or 10×8 view lens.—Address, W. A. BROOKS, Photographer, Frouce.

Rustic stile, head and body rest, and office copying press; want pneumatic time shutter or wide-angle lens.—Address, W. CUTTNER, 31, Highgate-hill, London.

Wanted to exchange, interior and exterior backgrounds for two others; also old single view lens, by Postings, and ship mast, for posing chair or backgrounds.—Address, BROOKS, Photographer, Frouce.

Wanted, first-class detective camera; will exchange lantern slides (Woodbury and others), Chadwick's oxygen generator, or splendid forty-cell medical battery.—Address, W. A. BEZANT, 12, Victoria-terrace, Leamington Spa.

Various lenses, cameras, electrical apparatus, gas bag, backgrounds, and other apparatus, in exchange for a seven or eight-inch single or double compound condenser, mounted or unmounted.—Address, WALSLEY, Bold-street, Liverpool.

Will exchange a leather pocket case of drawing instruments by Shanley, of London, for a rapid rectilinear lens of seven-inch focus, by any first-class maker, iris diaphragm preferred.—Address, WILLIAM HENRY PRATT, Regent-lodge, Regent-street, Nottingham.

I will exchange one volume each of *Illustrated London News*, *THE BRITISH JOURNAL OF PHOTOGRAPHY*, *Ally Sloper*, and half-plate rapid rectilinear lens, for a good whole-plate camera or lens.—Address, ARTIST, 10, Anberley-villas, Russell-road, Bowes-park, N.

Will exchange first six volumes of *Journal of Microscopy and Natural Science* for a Newman or a Kershaw shutter to fit a lens with inch and a half hood or under; also a well-bound edition of Darwin's *Origin of Species* for smaller shutter by good maker; or will exchange both works for a quarter-plate Eastman-Walker roller slide.—Address, ERNEST LAMBERT, Photographer, Bath.

Answers to Correspondents.

• Communications relating to Advertisements and general business affairs must be addressed to "H. GREENWOOD & Co.," 2, York-street, Covent Garden, London, W.C.

All matters for the text portion of this JOURNAL, including queries for "Answers" and "Exchanges," must be addressed to "THE EDITOR," 2, York-street, Covent Garden, London, W.C. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.

PHOTOGRAPHS REGISTERED:—

R. Symons, Tenby.—Photograph of the Swansea Wesleyan District Committee at Tenby, May 15, 1889.
R. Cash, Ipswich.—The "Phantom photograph" of the River Gipping, Ipswich.

W. HARDING WARNER.—Received.

KAMSET.—Yes, if they are on private property. Not otherwise.

SIR J. D. MARWICK.—Thanks for the hint, which shall be acted upon.

R. H. ELDER.—We shall submit your letter to a friend in France, and publish the reply.

Z. BLUNT.—Ordinary water colours mixed to match the tone of the prints, whatever that tone may be.

J. W. COULBOURN.—We have not the work in question on our shelves, so cannot say who are the publishers.

A. MILLER.—A bad case of halation. On the next occasion either back the plates or procure some more thickly coated.

S. A. J.—Tools for grinding lenses, so far as we are aware, are not articles of commerce. Any engineer will construct them for you if you give him the curves you require.

HENRY WILLIAMS.—There are really so many instantaneous shutters in the market, the majority of which will do all you desire, that we could not attempt to recommend any particular one.

A. G. FIELD.—It is impossible to say whether the salt sent is pure or not without making an analysis.—2. No.—3. First find out what is the impurity, if any, and then describe it to dealer. That is the only way you can complain.

W. GUTTENBERG.—We do not think that professional photographers are likely to suffer from the introduction of automatic machines for taking and delivering portraits by dropping a certain number of coins into such machines.

IN A FIX.—To obtain more density in copying, increase the proportion of pyrogallic acid greatly and use bromide freely. It is quite possible that, for your purpose, the hydroquinone developer will be best. Try it, and give it plenty of time.

GWENT.—1. It prevents oxidation of the pyrogallic acid.—2. The proportions you use are all right.—3. The white deposit will do no harm.—4. The stops are, or should be, marked according to the equivalent focus of the lens—and not the back focus.

W. N.—There is so very little platinum in the paper as to render it altogether inexpedient to attempt its recovery or conversion into the chloride, which salt can be much more economically and easily prepared by dissolving the metal (which is now cheap) in *aqua regia*.

W. BISHOP.—You had better write to "the powers that be" at the different places at which you wish to photograph. They will tell you the proper parties to apply to. You will get the names from the *Post Office Directory*. We only know one or two on your list.

JAVA.—1. Unless the rain water is caught in the open country, as a rule it is less pure than the ordinary water supply, and its purification is scarcely worth the trouble.—2. In all cases, if sufficient exposure be given, the image will be visible. It may be used for printing out.

R. C. HARDING.—Opal glass with a polished surface may be had from any house that makes a speciality of the ordinary article. The polished kind is known under the name of patent plate opal. It is not so suitable for pictures which have to be coloured as the matt surface; it is also much more expensive.

G. NORREXY asks if there is any way by which a negative can be dried more quickly than allowing it to dry spontaneously.—Certainly. If the wet negative be immersed in methylated spirit for a few minutes and afterwards transferred for a similar time to a fresh lot the negative can then be dried before the fire or by the sun in a very short time.

W. H. JONES.—Your pair of plano-convex achromatics will best serve your purpose by mounting them close together, their convex surfaces next to the sensitive plate, and a diaphragm about an inch in front of the outside one, that is, next to a plane surface. The lens for a finder may be formed of a cheap single lens, which need not be achromatic.

CONSTANT SUBSCRIBER asks: "How long should a bichromate of potash bath last? Should it be made fresh for every batch of carbon tissue? When sensitised, how long should it keep soluble?"—The sensitising bath may be used several times, but it should be discarded when it begins to acquire a brown tint. If the tissue is not dried too slowly it should keep soluble for a fortnight or more, that is, if it be kept with ordinary care.

F. WALLER.—Thanks for letter and drawing. We have long been acquainted with Brewster's suggestion, which was afterwards more fully elaborated by Sir John Herschel, and it has still more recently been carried into practical effect as a telescopic object glass in Germany. But the principle involved in the construction of the photographic lens referred to is somewhat different, and was explained by Goddard when he constructed his double periscope lens in 1861.

ERNEST LAMBERT wishes to know if there is any way to get an under-exposed negative strong enough to print from without the usual long time in the developer. He says he is "continually annoyed at having to keep on developing an immense time."—There is no way of dealing with an under-exposed negative but patience in the development. If this be hurried the result will suffer. Moral: Do not under expose. We are not familiar with the manufacture of inks. Consult one or other of the receipt books which treat on such matters.

WM. S. (Guildford).—The spots on the prints enclosed all have a black speck as a nucleus, and this shows, in many instances, more strongly on the back of the paper than it does on the front. This would seem to indicate that the paper itself contained particles of foreign matter which reduced the silver. We should advise you, after sensitising and drying some of the paper, to examine it in a good light and see if the spots are discernible at that stage. Also slightly tint a piece by a brief exposure to light. If the spots show under these conditions you had better try another sample of paper.

A. NORFOLK AMATEUR writes: "I have often heard that better tones are obtained on paper which is sensitised at home than on the ready sensitised of commerce. During the last week or two I have been sensitising my own paper by floating it for two minutes on a bath of sixty grains of nitrate of silver to the ounce of water and nothing else. I find with this paper that I get far better tones than I could with any paper I have tried before. But, at times, I am troubled with marbled-like stains on the paper, like enclosed, but only with occasional sheets. Can you account for this?"—The marbling is caused by floating the paper when there is a scum upon the solution. If the solution, after use, is allowed to stand for any length of time in the dish a scum is sure to form upon the surface. When this is the case, it should be removed by drawing a strip or two of blotting paper over the solution before any more paper is sensitised. The finished prints are very good indeed. The tone is excellent.

EXPERIENCE puts the following queries: "1. What the strength should be of the strengthener used for strengthening a sensitising bath of sixty grains?—2. What to add to get rid of the acid in the silver bath?—3. What advantages are gained by sunning the sensitising bath?—4. What advantages are got by adding liquid ammonia? and what quantity?—5. What advantages are got by adding methylated alcohol? and what quantity?—6. How many sheets can be done in a sixty-grain bath before it is necessary to add any strengthener? and what quantity should be added?—7. Is it necessary to put in kaolin every day after use to rid the bath of impurities?"—In reply: 1. Any strength will do so long as sufficient solution is added to bring the bath up to the sixty grains to the ounce. Use an argometer.—2. A dilute solution of carbonate of soda.—3. The organic matter becomes precipitated.—4. None if the acid be neutralised by carbonate of soda.—5. Said to prevent blisters—a drachm or so to the ounce.—6. All will depend upon the size of the sheets and the quantity of solution.—7. Not unless the solution is discoloured.

R. C. McLEOD says: "May I ask if there is not a mistake in your statement that five grains of bromide of potassium to the ounce is what you recommend for a normal developer (ferrous oxalate)? I fancy you must mean five drops of a ten per cent solution, which I find gives very good results with England's slow plates.—In reply: We mentioned three grains (not five), which is not excessive with many plates, especially when employing the energetic developer we recommend. We have had no experience with the plates named under iron development.—"What is the relative power of soda (common washing) and potash? You mention that of purified crystals and the anhydrous but not the washing soda."—Ten grains of washing soda if not effloresced, and the same quantity of pure crystals, are equivalent to 4.75 grains anhydrous carbonate of potash. In reply to your question regarding the French Custom Houses and photographing in France, see a letter from Mr. Albert Levy in our issue of April 19. With regard to the charge of chlorate of potash, it is not advisable to fill the retort more than one-third full, although that rule is frequently broken.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—Technical meeting at 5A, Pall Mall East, on Tuesday, May 23, at eight p.m.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, May 29, 1889, will be on *The Keeping Qualities of Bromide Plates*. Saturday outing at Chigwell. Trains from Liverpool-street.

THE *Revised Catalogue* of J. Robinson & Sons, 172, Regent-street, W., which we have just received, is replete with good things manufactured or sold by this firm. It contains numerous illustrations.

THE Tondeur developer (sold by Mr. Sharland, Thavies Inn) is chiefly remarkable for having eosine as one of its components, hydroquinone being the active agent. Without waiting to inquire the part played by the eosine, we tried a sample sent us and find that it gave a good clean negative of fine colour.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1517. VOL. XXXVI.—MAY 31, 1889.

MEANS OF PRODUCING COLD.

THE approach of summer, with a possible accompaniment of heat, induces ideas respecting the production of cold. Of the many uses of refrigeration during a torrid, sultry, tropical state of the atmosphere it is needless here to speak; those who work with gelatine plates, and especially those who have to manufacture them when the thermometer is in the vicinity of the nineties, appreciate full well the desirableness of being able to convert dog-day heat into hyperborean chill, and the great value of any means by which such conversion may be effected. The production of cold is merely the abstraction of heat from the body that is being operated upon. The means for effecting this have of late been undergoing advances towards perfection; it is only the other day since we saw in a well-heated manufacturing engineering shop a considerable quantity of mercury frozen quite solid while it was exposed to the warm atmosphere of the workshop. This, it must be admitted, indicates a high advance in the art of congelation.

Concerning methods of producing cold, there are three of which we shall here speak. The first is the well-known one of imparting cold to water by dissolving in it certain substances, of which there are none which in our estimation can vie with nitrate of ammonia for general efficiency and undoubted convenience. In addition to this, it is also the most economical of all saline bodies, as it is not wasted during use, but may be employed over and over again. If a thermometer is placed in a tumbler of water, at, say, 50° Fahr., and some crushed crystals of the nitrate of ammonia are then thrown into the water, the column of mercury will be found to descend with singular rapidity until it reaches 26° to 27° below the freezing point, or about 5° Fahr. There are several mixtures which can be made by which a much greater degree of cold can be obtained, but these when once used cannot be used again. But with the ammonium nitrate it merely suffices to pour the solution out into an evaporating dish after being done with, and having driven the water off by heat, or otherwise, place the crystals into a bottle, when they are ready for future use in a similar way.

We here give an illustration of one way by which the knowledge of the above-mentioned fact may be serviceable. We had once some gelatine plates to develop in a semi-tropical country at a time when the heat was intense and the water so warm as to endanger the film during development. We placed the developing solution in a japanned tin developing tray, and placed that tray inside of another slightly larger, and in the bottom of which we scattered a few crystals of nitrate of ammonia, afterwards pouring in a little water. This reduced the previously high temperature of the developer to one that

could not possibly affect the too soluble gelatine of which the film was composed.

A second system for the production of cold consists in the compression of air. Thus compressed, and forced into a reservoir, it becomes heated, as every one knows who is familiar with the working of an air gun. But when cooled down again, before it is suffered to escape, its expansion is attended by great cold. "If when compressed it is allowed to cool down to the ordinary temperature and then to escape, it will be cooled below that temperature just as much as it was heated by compression. Thus, if in being compressed it had been heated 100°, say from 60° to 160°, and then allowed to cool to 60°, on escaping it will be cooled 100° below 60°, or to 40° below zero, which is the temperature at which mercury freezes." This is the principle of the cold air chambers now so extensively employed on shipboard for the transport of frozen provisions from Australia and New Zealand.

The ingenious photographer who dreads the preparation of gelatine plates in hot weather will in this discover the means by which he may be enabled to keep his coating room at fifty degrees or sixty degrees during the most sultry months of the summer, aided by a small gas or petroleum engine. We have devised a most perfect means of effecting this, by manual power if desired, and that only applied at occasional intervals, but a detailed description of it would be out of place in this article.

It is well known, by some at any rate, that the condensation of certain vapours is attended by extreme cold. On the principles actuating this phenomenon we do not here enter, but confine ourselves to giving a brief description of one of the machines—if machine it may be called—by which the principle has obtained its latest outcome. This apparatus, which has received the trade name of "The Arktos," consists, roughly speaking, of a tube bent \cap -shape, at the end of one limb being a reservoir which contains strong liquor ammonia. This ammonia should be as strong as possible; although that so well known among photographers as 880 will do, yet Mr. Loftus Perkins, the inventor of the apparatus, informs us that he prefers it much stronger—say 875; a strength he certainly manages to obtain. This bent tube has its air abstracted, and is hermetically sealed, and heat is applied to the ammonia reservoir, by which the ammonia liquid parts with its gas. When the source of heat is removed and the gas re-enters the water, the cold is produced at the farther limb of the apparatus in a degree of such intensity as to cause a deposition of the moisture in the atmosphere in the form of dry snow. So great is the cold produced that, as previously hinted, we have seen, and that, too, in a warm room, the solidification of mercury in

the vessel into which the end of the tube was dipped. One end of this tube may be called the boiler, and the other the refrigerator; and a condition of success is that the connecting pipe between the two shall be kept cooled while the boiler is being heated, so that all gas passing to the refrigerator may enter it in a comparatively cool state. When this is used on a large scale it suffices that a fire be applied for two or three hours once a day, by which the refrigeration is rendered singularly perfect. There are minor mechanical details connected with this apparatus, but the general principle is as above stated.

Thus is solved the problem of a process for attaining cold and ice without mechanical aid, and as the inventor says, "Its abounding efficacy is made evident in its freezing of mercury in the open air."

FERROUS OXALATE.

Our mention, in the closing paragraph of an article on *The Development of Transparencies* a fortnight since, of the "original method" of making the ferrous oxalate developer by dissolving oxalate of iron in hot solution of oxalate of potash, seems to have puzzled some of our readers, and we cannot help confessing to a feeling of considerable surprise that so little acquaintance should be exhibited with the real composition of a developer so commonly used and so little recollection of past history.

It is now some twelve years since Mr. M. Carey Lea, then a regular contributor to our columns, first published his formula for a new developer, which has long borne the name that heads this article, and though the process now generally adopted in its preparation was given as an alternative method, Mr. Lea more particularly recommended what we have termed the "original" method, because it was the one that was adopted and remained in use for several years. It is, indeed, the more scientific method, and the one calculated to give the best results, since, when properly carried out, it constitutes a pure solution of oxalate of iron in oxalate of potash of the highest degree of concentration, and without any artificial restrainer.

The modern method is simply one of convenience, and though very workable, is comparatively but a makeshift, as by the mixture of sulphate of iron and oxalate of potash a compound is made of very variable strength and composition, and containing a large proportion of active restrainer in the form of sulphate of potash, formed by double decomposition. The solution never contains the full quantity of oxalate of potash it is capable of holding, because even if a saturated solution be employed to start with, a great portion of the potassium salt is converted into ferrous oxalate, leaving only perhaps a half-saturated solution of oxalate of potash to dissolve the iron. This, considered in conjunction with the presence of the sulphate of potash, renders it clear that the original method must give by far the more energetic developer.

For the benefit of those who seem to be ignorant of this method, we will shortly describe it. The same ingredients only are required, namely, ferrous sulphate and oxalate of potash, but the plan of mixing them is different. In the first place, weigh out three parts—say, ounces—of neutral oxalate of potash and five parts, or ounces, of sulphate of iron, and dissolve them separately in any convenient quantity of water, not however making the solutions too dilute. When dissolved, mix the two solutions. At first the mixture will

take a bright yellow colour but remain clear, and it may be some time before any precipitate begins to form, and then it proceeds but slowly; if the vessel be set aside, however, for a few hours, a dense, bright yellow precipitate will settle to the bottom, leaving the supernatant liquid perfectly clear and colourless. This deposit is the oxalate of iron or *ferrous* oxalate (for the *per* oxalate or ferric oxalate is a soluble salt), and the clear liquid contains only sulphate of potash, which is poured away as practically useless. Pour off the upper liquid and stir the precipitate well with fresh water, and allow it to settle again, which it will now do in a very short time. Repeat this washing, and then the yellow powder may be collected on a filter and dried, in which state it may be preserved indefinitely.

The next operation, the making of the developer, is conducted as follows:—Take, say, a quarter of a pound of oxalate of potash, and pour on to it from a glass flask or beaker ten ounces of distilled or rain water, and heat the vessel until the salt is dissolved. While still hot, add to the solution and stir well some of the yellow oxalate of iron. At first a mere or less deep red, clear solution will be formed, but as more of the oxalate is added the mixture will become muddy and of a pale colour like the oxalate. As this dissolves, however, the deep colour appears, and this will be a guide as to the quantity of oxalate to add. When the solution retains the pale, muddy appearance, after stirring for some time, it may be considered to be saturated, and is then set aside to cool, when a few crystals and a quantity of reddish-brown "mud" will be deposited, leaving a rich, deep red, clear solution of oxalate of iron in oxalate of potash.

A single experiment will suffice to give an idea of the approximate quantity of yellow oxalate to add to a given quantity of solution, or the latter may be poured on to a considerable excess of the powder and boiled for two or three minutes, then allowed to cool and clear. In this case the undissolved oxalate of iron should be at once washed in two or three changes of hot water and re-dried, or it may be preserved in the moist state.

The solution so formed constitutes the ferrous oxalate-developer in its purest and probably most energetic form, and for ordinary purposes will no doubt be all the better for a considerable addition of restrainer, though for extremely rapid work it may be employed in its nearly pure state. In this form, if properly restrained, it gives far stronger and richer negatives, as well as purer and finer blacks in positives, than can be obtained by any proportions of the mixed solutions of iron and oxalate of potash as usually employed, hence those who appreciate a rich-coloured print will do well to "prospect" this developer.

But the solution so formed does not long retain its energy under ordinary circumstances, being even more liable to change than that made by the simple mixing of the two solutions. Many dodges have been suggested for its preservation and regeneration when oxidised, but they are mostly only palliatives. The solution should always be kept in daylight, which prevents the oxidation, or reconverts the ferric salt to the ferrous condition when it has been oxidised. Another plan consists in keeping a hank of bright iron wire immersed in the solution. A third in adding small quantities of tartaric or oxalic acid and placing in a strong light; while in a fourth the deoxidation is performed by means of a solution of sulphite of soda.

The plan, however, which we have found most efficient as

well as the most scientifically correct, is one that is unfortunately rather troublesome, since it depends upon the employment of ferrous sulphite, which is not readily obtainable commercially, and, consequently, has to be made. This, however, is not a formidable operation. The ferrous sulphite is itself an insoluble and unstable salt, but it is freely soluble in excess of sulphurous acid, the solution apparently keeping well. The mode of preparation we adopt is as follows:—

A quantity of ferrous sulphate is precipitated by means of carbonate of ammonia, and the semi-gelatinous mass washed as well as may be to free it from the sulphate of ammonia, though this is a very tiresome job. The presence of a trace of the sulphate, however, is not of great moment. An apparatus for the generation of sulphurous acid is next provided. This consists of a bottle provided with a cork, through which a couple of holes are pierced—the one to carry a funnel for the introduction of acid, the other a bent tube to lead the sulphurous acid over. In the bottle place a quantity of crystals of a soluble sulphite or bisulphite, or even of "hypo," and cover them well with water. Insert the cork with its funnel and tube, and let the latter dip into the vessel containing the precipitated ferrous carbonate. Now, by means of the funnel, add, a few drops at a time, strong sulphuric or hydrochloric acid, which will liberate SO_2 in the form of gas, and this passing over into the carbonate of iron converts it into sulphite, with change of colour from dirty green to greyish brown. Continue the passage of sulphurous acid, however, until the contents of the iron vessel become clear and nearly colourless, when the operation is complete. A funnel with a glass tap in the stem, known as a "separator," should be used; if not provided with the tap, some means must be adopted for plugging the aperture after each addition of acid to prevent the escape of sulphurous acid that way.

A little of this solution added to the ferrous oxalate developer, when freshly made, will arrest its oxidation, as no sooner does the ferrous oxalate become ferric—if it ever does in the presence of ferrous sulphite in excess—it is decolourised by the sulphite, which, being converted into sulphate, is acted upon by a portion of the oxalate of potash, and reconverted into ferrous oxalate and precipitated as such if in excess. In this manner a constant interchange of elements may be supposed to go on until the sulphite is exhausted, the only effect produced being a precipitation of ferrous oxalate equivalent to the sulphite originally added. As the ferrous sulphite is itself a powerful developer, it must be used sparingly or it will produce fog; the sulphurous acid, too, has a tendency in that direction, but this can be kept in check by the use of restraining bromide.

THE METRIC SYSTEM.

Still advances the tide of reform in our system of weights and measures, and it is with gratification we record that two of our most active London Societies—the Photographic Club, and the London and Provincial Photographic Association—have signified their intention of adopting the metric system.

In a former article (March 15, p. 174) we have explained the meaning of the Greek prefixes employed to denote the multiples of units and the Latin prefixes which denote their fractional parts. We now enter a little into detail respecting those weights and measures pertaining to the operations of the photographer. As we have already mentioned, the Greek prefixes

denote the multiples of the measure to which they are united. Thus:—

Metre	equals	1 metre.
Dekametre	"	10 metres.
Hectometre	"	100 "
Kilometre	"	1000 "
Myriametre	"	10,000 "

In the same manner the Latin prefixes denote subdivisions, as will be seen by the following proportions:—

Metre	equals	1 metre.
Decimetre	"	$\frac{1}{10}$ "
Centimetre	"	$\frac{1}{100}$ "
Millimetre	"	$\frac{1}{1000}$ "

For general purposes it will be found to be sufficiently near to consider a metre as $39\frac{1}{2}$ inches, and a decimetre as $3\frac{1}{8}$ inches.

In order to aid in the more ready introduction into practice of the decimal means of calculating, we will give the relative values in inches from the millimetre to the metre:—

Millimetre.	Metre.	Inches.	Centimetre.	Metre.	Inches.
1 =	·001 =	·03937	6 =	·06 =	2·3622
2 =	·002 =	·07874	7 =	·07 =	2·7560
3 =	·003 =	·11811	8 =	·08 =	3·1497
4 =	·004 =	·15748	9 =	·09 =	3·5434
5 =	·005 =	·19685			
6 =	·006 =	·23622	Decimetre.	Metre.	Inches.
7 =	·007 =	·27560	1 =	·1 =	3·9371
8 =	·008 =	·31497	2 =	·2 =	7·8742
9 =	·009 =	·35434	3 =	·3 =	11·8113
			4 =	·4 =	15·7484
Centimetre.	Metre.	Inches.	5 =	·5 =	19·6855
1 =	·01 =	·3937	6 =	·6 =	23·6226
2 =	·02 =	·7874	7 =	·7 =	27·5597
3 =	·03 =	1·1811	8 =	·8 =	31·4968
4 =	·04 =	1·5748	9 =	·9 =	35·4339
5 =	·05 =	1·9685	1 metre =		39·3685

But what is the metre itself? It is the standard length, of which the $\frac{1}{10000000}$ of a quadrant of the earth's meridian is equivalent to 39·371 inches.

The standard of the weights by which chemicals are calculated is the gramme, which is, roughly speaking, the equivalent of 15½ grains. It is subject in the same way, as previously mentioned, of adding a Greek or Latin prefix to denote its multiples and subdivisions of the same.

The unit of fluid measurement is the cubit centimetre, based upon the gramme, the weight of one gramme of water at maximum density being termed one cubit centimetre.

The proportions of fluid measurements on this basis will be apparent by the following table:—

Names.	No. of Grammes.	Weight of Water.	Avoirdupois Weight.
Millier or tonneau	1,000,000	1 cubic metre	2204·6 lbs.
Quintal	100,000	1 hectolitre	220·46 lbs.
Myriagramme	10,000	10 litres	22·046 lbs.
Kilogramme or kilo	1,000	1 litre	2·2046 lbs.
Hectogramme	100	1 decilitre	3·5274 ozs.
Dekagramme	10	10 c. centimetres	·3527 ozs.
Gramme	1	1 c. centimetre	15·432 grs.
Decigramme	·1	$\frac{1}{10}$ " "	1·5432 grs.
Centigramme	·01	10 c. millimetres	·1543 grs.
Milligramme	·001	1 c. millimetre	·0154 grs.

Into the equivalents of miles, acres, and gallons we will not enter, as they are entirely out of the range of photographic requirements.

The following table will perhaps aid those desirous of acquiring

giving a knowledge of the relations of the various measures and capacities:—

1 litre	= 1000 c.c.	(liquid measure).
1 kilogramme	= 1000 grammes	(solid weight).
1 metre	= 1000 millimetres	(length measure).
1 litre	÷ 100 = 10 c.c.	
1 kilometre	÷ 100 = 10 grammes.	
1 metre	÷ 100 = 1 centimetre.	

It may be said that all this is somewhat technical, but the proportions in the formula given below will simplify matters.

A	100 c.c.
B	5 decigrammes.
C	1 gramme.
D	1 centigramme.
E	1 kilogramme.
F	1 litre.

In order to ascertain the relative quantities from an English point of view, it is necessary to have a starting point. As it is immaterial what the quantity to be mixed is, we will presume that the largest measurement is, say, 1000 ounces.

It is of multiples and parts of this as a standard that we must work, and all the proportions will be the same if it had been termed ten instead of one thousand ounces.

As a litre and a kilogramme are the same equivalent, we have—

E	1000 ounces.
F	1000 „

A	being 100 c.c.	is $\frac{1}{10}$ of a litre, and will be 100 ounces.
C	„ 1 gramme	„ $\frac{1}{1000}$ „ kilogramme „ „ 1 ounce.
B	„ 5 decimetres „	$\frac{1}{2}$ „ gramme „ „ $\frac{1}{2}$ „
D	„ 1 centigramme „	$\frac{1}{100}$ of A „ „ 5 grains.

To those who have been used to halving, quartering, and counting by the dozen, this system will at first appear rather strange, but as soon as the principles are thoroughly understood the great advantages will become manifest. Any one used to the subdivisions of pounds, shillings, and pence, upon going abroad, say to America, finds at first the decimal system of currency in use there rather peculiar, but only until the relative proportions are thoroughly understood, when it at once becomes apparent that the system is of greater simplicity than that in use in this country, and thus will it be with the metric system of weights and measures.

Fluid measures of various capacities, graduated in English and also in metric values, have now been introduced into commerce, and these, together with the requisite weights, are to be had cheaply.

“HYPO” AND “HYPO” SOLUTIONS.

A SLIGHTLY foggy sentence in an article upon hyposulphite of soda, in Watt's *Dictionary of Chemistry*, has been made the text for many a lecture and a peg for trade purposes; we are afraid to hang up many an excuse for sophisticated samples of the salt, commonly so-called. The exact wording of the sentence we refer to (it occurs in vol. v., p. 636), is as follows:—“The aqueous solution cannot be preserved unaltered, even in closed vessels, but deposits sulphur, and is partly converted into sulphate of sodium; in contact with the air, it is gradually but completely oxidised into sulphate.” The question is, “Does the last assertion refer to the salt in crystals or the solution?” We take it that the salt in solution is undoubtedly intended to be spoken of. To put the matter to the test, we obtained a

sample of hypo crystals of known purity, and exposed it to the air for a period of twelve months in a room whose temperature fluctuated exceedingly, and at the end of the time it was, excepting a coating of dust, exactly in the same condition as when first exposed. There is thus established a very ready means of ascertaining whether a number of suspected crystals are pure hypo, or contain a proportion of ordinary sulphate of soda, the Glauber's salts, largely used for veterinary purposes. (*En passant*, it may be stated that hypo itself had a reputation for a short time among veterinarians. At the time when the rinderpest was making such havoc among the cattle of this country, hyposulphite of soda was extolled as a complete prophylactic, and became instantly in such demand as for a time to affect the market price of the salt. At the present time, indeed, it has a certain limited use in medicine.) It suffices to place the crystals for a few days in a fairly dry and warm room and observe whether they effloresce or not. If they exhibit a white surface, it may be taken as a certainty that sulphate is present, while an absence of change implies that the sample is free from the salt.

The bearing of these simple facts is important. Glauber's salts are not much more than half the price of “hypo” crystals, hence largely adulterated samples of the latter might be sold at the price which true “hypo” would cost a manufacturer to make, and would then leave a profit. The practical effect of such adulteration is much more than the dishonesty of the transaction, as above all things it is, in fixing prints, essential to use a liberal quantity of “hypo” for its staple photographic use, the fixing of albumenised paper prints; and if the proportion, too frequently brought to a minimum on account of business competition, be reduced below the point of safety, we thus have an insidious means of interfering with the permanency of the prints so treated. As the reputation of this class of work is already on the wane in public estimation, it behoves every photographer to look into the matter, and if he finds his cask of hypo crystals beginning to effloresce before he has half finished it, he may be sure that he ought to use a larger proportion in his fixing solutions. As to the business relations betwixt him and the dealer who supplied it, that is not a question for us here to enter upon.

Turning now to the solution of hypo itself, we must read the sentence from Watts as being a very early indication of the un wisdom of keeping solutions of hypo for any length of time before use. It is not necessary at the present time to explain the exact method in which the use of such changed solutions would be injurious. It is sufficient to say that any sample of solution of hypo that has undergone decomposition is unsafe for fixing prints or negatives if permanency be any object. The hypo sulphites of silver formed during the operation of fixing are of themselves so very unstable, and liable to change in the light always, and, in presence of an insufficient amount of hypo, in the dark also, that it would be folly to introduce another disturbing element.

The strange tendency to use so-called “saturated solutions” is especially unwise in the case of the chemical under consideration, as a day or two would, unless an undue amount of time and attention were given, be quite needed to ensure saturation, the first steps would be taken towards decomposition, and as it is to be assumed that solutions so made would naturally be stored away for future use, there would then be introduced a second incentive to change.

With regard to paper prints, it is, however, we believe, the common practice to adopt the only proper method, viz., the

making of fresh solution every day, or each time a batch of prints is got through, and the chief neglect of measures of safety is shown with regard to the fixing solution for negatives, which in so many places are unwisely allowed to remain in use till quite "exhausted." Seeing that this is so, the question naturally asked is, Can the change be arrested altogether, or prevented? Fortunately, hyposulphite, or, as it is now more accurately termed, thiosulphite of soda, is a chemical of some considerable analytical importance, and this question can, to a certain extent, be replied to by reference to existing authorities on analytical matters, and their opinions shall be put before our readers. As it would unduly prolong our remarks to quote these opinions at length at the present time, we will defer describing these opinions to a future issue.

PHOTOGRAPHERS, particularly those who take their cameras abroad with them, will hail with satisfaction what took place in the House of Lords on Friday last. Lord Ribblesdale asked the Government whether they considered the Custom House regulations, with respect to undeveloped photographic plates, were reasonable. He said a friend of his arrived at Plymouth, some time back, from a foreign port with some undeveloped negatives. There was no dark room in which the plates could be examined. Explanations and entreaties were in vain, the Customs officials were obdurate. Eventually, the plates were then locked up for the night and the owner delayed. The next day the use of a dark room was obtained at a local photographer's, and the plates duly examined and passed. The Marquis of Salisbury's reply was one which will meet with the approval of every travelling photographer; and it is by no means complimentary to the official who caused the inconvenience. The noble Lord said: "It falls to my lot to defend the Government, and I defend it by saying that this particular Custom House officer appears to be a man of inconceivable stupidity. I hope a misadventure of this kind will not happen again." In conclusion, Lord Salisbury remarked, somewhat sarcastically, "I am sorry that the knowledge of advancing science has spread so little among certain branches of Her Majesty's service."

LORD SALISBURY, it is well known, takes a lively interest in all pertaining to every branch of science—photography included. It can, therefore, well be imagined that any unnecessary inconvenience in its pursuit, caused by an over officious Government *employé*, would certainly meet with the reverse of his approval. It is a fortunate circumstance that the gentleman who experienced the annoyance at the Plymouth Custom House had a "friend at court" who could bring the grievance so prominently forward to the benefit of all. Possibly, had the trouble been caused to a more humble individual, or perhaps to a professional photographer, to whom time is money, and whose pecuniary loss would be greater than in the case cited, nothing would have been heard of the matter. Thanks are certainly due to Lord Ribblesdale for taking up the subject.

REGULATIONS have now been issued to all Custom Houses to the effect that, if sensitive plates are to be examined, "they should be examined in a dark room by the light of a red lamp." At some ports dark rooms have for some time been provided, so that, if considered necessary, undeveloped plates can be examined without risk of injury. Now, however, it is to be the rule at all ports. Every one would, as a matter of course, prefer not to have his plates opened at all. But it must be confessed that a large number of contraband articles could very well be smuggled through the Customs disguised as packages of dry plates. However, it was suggested in the House of Lords that a declaration, made under certain conditions, that the parcels contained nothing but *bond fide* photographic plates might be accepted. Such a thing might, we imagine, easily be arranged. As it is, it is seldom that the Customs officials really demand to see the plates.

THE unusually hot weather for the season experienced last week caused considerable trouble to those workers in gelatine photography

who were not prepared for it. In collotype, Woodburytype, and other processes in which bichromated gelatine is employed, serious inconvenience is often met with in an abnormal rise and temperature. One plate maker remarked to us somewhat dryly, that "using plates and making them this weather means two totally different experiences."

REMOUN has it that an attempt is being made by certain manufacturers to combine together to raise the price of dry plates, and that, too, considerably. That the present price of plates is barely remunerative, except when working on an extensive scale, systematically, and with the greatest economy, one can readily believe; but if the price be raised to the extent we have heard mentioned, there is little doubt that fresh manufacturers will quickly enter the market. A number of small makers have succumbed to the present keen competition, but they may again enter the field, and possibly be more successful in the future. If a rise in the price be deemed necessary, manufacturers, in their own interests, we think, will do well to take this point into consideration and not make it too great; certainly not so great as that rumoured. Of course, every one knows quite well that the present prices are remunerative to some manufacturers.

WILL the name "Kodak" eventually become a generic one for detective cameras? We put the question inasmuch as we have, several times, heard the term applied by the uninitiated to different forms of detective cameras which in no way, either in appearance or principle, have resembled the widely advertised instrument. However, a rose will smell as sweet by any other name, and "detective" is not altogether an euphonious title for a camera.

COTTONS entitling their holders, when a certain number have been obtained, to "presents" are common enough among tea grocers, and the like. Until recently we were unaware that anything of this kind was practised in connexion with photography. However, such appears to be the case. Passing the shop of a tobacconist, who appears to combine photography with the tobacco business, we saw the announcement that all purchasers of twopennyworth, and upwards, of goods would be presented with a coupon, and when a sufficient number of these were acquired the holder would be entitled to have his portrait taken gratuitously. There is novelty in the conception.

PHOTOGRAPHS of medals and coins are not always so satisfactory, when taken by many photographers, as could be desired. They are by no means easy subjects to depict photographically. Excellent photographs of them, however, are to be frequently met with in some of the publications in which numismatology is made a feature. It may not be generally known that these photographs are rarely, if ever, taken direct from the coins themselves, but from plaster of Paris casts, made specially for the purpose. The plaster employed is slightly tinted with burnt sienna, or similar pigment, to destroy its excessive whiteness, and thus render the casts specially suited to photography. This will fully account for the difference in the published photographs of this class of subject as compared with the work of an ordinary photographer when he is suddenly called upon to photograph the metallic articles themselves, as he frequently is with prize medals, for advertising purposes. When gold, silver, and bronze medals or coins have to be included in the same negative, and plaster casts of them are prepared, a difference should always be made in tinting the plaster. The casts from the silver should be made lighter, and those from the bronze darker, than the gold ones.

"THE INFLUENCE OF THE STEREOSCOPE."

MY notice has just been called to a weak and misleading article headed as above, over the initials "F. M. S.", in the columns of a weekly contemporary. As it occupies a portion of the space assigned to "Editorials," and as the initials are those of an "Editorial Contributor," the article in question goes forth to that portion of the photographic world which sees it as having the authority of one who is amongst the scribes.

It is, therefore, perhaps worth while to offer something in the nature of a reply to this, the latest and silliest of the tirades against Photography for the Stereoscope. "F. M. S." affirms that in the past stereograms have prevented the progress of photography in its fine art direction, and as an evidence of this he gives the opinion of an "old worker," who says that to his mind "there is nothing pictorial more valuable than a stereograph of some well-chosen view with a group of familiar friends in the foreground."

It may be, perhaps, worth while remarking here, that the world does not exist for the gratification of people who think with dreaminess and talk with obscurity about fine art, but that, on the contrary, fine art—notwithstanding the dreaminess and obscurity of its expositors—exists for the gratification of the world.

That some one man or some thousand men should regard a stereographic group in front of some well-selected view as the *beau idéal* of pictorial art is certainly no argument against the stereoscope, on the contrary, it is an evidence that the illusion of solidity which the instrument affords was in these instances so genuine and so enchanting as to altogether outweigh, as a source of gratification, the fine art efforts of the producer of the stereogram. This, however, is not a matter for surprise, for at the "time of day" to which "F. M. S." alludes the art status of photography, as a whole, was extremely low, and that not because photography was a "foe to graphic art," as the punsters of the time averred, but because, as a rule, men of artistic capabilities were too prejudiced to employ photography, and because (as "F. M. S." allows), "it took a man all his time to keep his silver bath in order" then.

There were, however, even in those days, some few who made artistic stereograms—of which I have examples before me now—pictures that charm, not only by the illusion of solidity, *obtainable in no other way*, but by the composition of their lines and the magnificence of their effects of light and shade.

Well do I remember how with almost bated breath I gazed for the first time upon a stereogram of a pool of water overhung by trees, whose shadows were thrown upon its surface, and whose forms were reflected in its depths.

The whole composition was a picture, double or single, but as seen in the stereoscope, the illusion of reality was so great as to be simply overwhelming at the time.

In the days when "the kitchen, the scullery, the tool house" were ransacked in search of "accessories," and when "watering cans, garden rollers, warming pans, pails and buckets, long brushes and short," were all pressed into the service of the stereographer (surely the warming pans were only metaphorically employed, and are in reality but coverings for hidden fire) who sought to "give relief" that heaven might bless his store, the single picture photographer, it should be remembered, frequently depicted our artisans in a grimy state and smoking "clays," sitting with a poor pretence of ease on furniture of terrifying grandeur disposed in front of an array of marble domes and battlemented towers.

Even these bizarre results, however, have not kept back photography as an acquisition to the arts; on the contrary, they have advanced it, by making the millions conscious that pictorial incongruity is absurd.

At the present time commercial dry plates and rapid processes give the operator a chance of attending to artistic excellence such as he had not in the days of yore. The consequence is that thousands upon thousands of photographs are now produced altogether superior, from an artistic point of view, to the average work of those who describe themselves as "artists;" and with that resurrection of stereography which is now inevitable, an order of pictures will most certainly obtain, totally eclipsing, from a fine art point of view, anything in the monochrome which the world has thus far seen.

Some people are still to be found who sneer at the "slides" of the lenticular stereoscope on the ground that they are small, as though artistic merits were a quantity, and could be measured by the yard; removed to a distance the largest pictures dwindle in their apparent size, and ultimately disappear, whilst the smallest, when viewed with proper appliances, and from a proper point, present a seeming size equal to that of the original itself, whether this be a man, a mole hill, or Mont Blanc.

Artists who trouble themselves to study aerial or geometrical perspective, do so that they may get something of the effects of solidity and distance in their works. The illusion of solidity, however, belongs to photography, and to the stereoscope alone, and it is from stereograms properly taken, properly mounted, and properly viewed, and from these only, that we gain a just and adequate idea of the dimensions of such objects as we properly describe as "Vast."

To decry the advantages of the stereogram, even from an artistic point of view, is merely to proclaim one's ignorance of its use.

W. I. CHADWICK.

ECHOES.

It is rather curious that in the same number of the JOURNAL in which I criticised a new "automatic" portrait machine hailing from France the description of another one appears, this time of British extraction, and oh! of such fearful and wonderful construction that it takes three pages of "THE BRITISH" to hold the specification. I hope it will repay somebody for the trouble of reading it through, though I must confess I got wearied long before I reached the eighth handle stage. All I can make of it is that it must be worth three-pence—the amount proposed to be charged by the inventors—to have your portrait taken by this machine, if only for the sake of the gymnastic exercise provided in turning the various handles. But surely the inventors have committed a great oversight in not providing a ninth handle, by means of which to let down an opaque screen to shut off the victim temporarily at least from the vulgar crowd.

I have never ventured to "try my weight" automatically for fear of the "B. P.," which, I believe, is the slang term for "British public," but the very thought of publicly and "automatically" "portraiting" myself at, say, Charing-cross Station, brings out a cold perspiration. I can fancy the anxiety that would be exhibited by the rapidly swelling crowd to see the result of the turning of each handle; the eagerness to read the fresh directions brought forward by each such operation, only rivalled by the eagerness displayed by the bystanders to read all the day's messages when some *bonâ fide* or merely curious one drops a penny into one of the automatic message cabinets. Yes, I can imagine all that anxiety, blended with a certain amount of kindly feeling shown in the desire to assist with advice at each operation, as well as suggestions as to the personal appearance of the sit—I mean victim—and possible improvements. My imagination can compass all this, spread over a very *mauvais quart d'heure*, but it does not rise to any attempt at description of the frantic struggle that would ensue to see the result, nor even to what that result would be like under the circumstances. I think it would possibly operate well for the machines and their owners if, after securing the "coppers," every portrait turned out a failure. The specification is worth the money!

I should like to ask Mr. Cosmo Innes Burton—after reading his article on *The Preservation of Solutions of Pyrogallol—Cui bono?* After telling us that the effects of caustic soda, potash, and ammonia upon pyro solution are so well known as to require no description, and that the carbonates behave in a similar manner, he proceeds to describe his experiments with a large number of substances that no photographer who was a chemist would ever dream of employing as preservatives or anything else. Why the article was written, unless for want of something better to do, puzzles me.

By the way, is the writer of the leaderettes on the subject of the overweight of pyro in ounce bottles correct in mentioning so large a possible excess as twenty to thirty per cent.? I venture to think that, cheap as pyro has become, the dealer who retailed it so carelessly would soon have to put up his shutters if he conducted his whole business on the same scale. It does not follow that because a thing is cheap it can be given away at that rate. In these days of "cutting" prices—and no one is a better exemplar of how close they can be cut than the photographic dealer—it is necessary to weigh even cheap things carefully if a profit is to be made, but of course, if the object is only to give away chemicals in order to secure customers for worthless cameras at a high price, the system is plain enough. But even then I do not think that the danger to the consumer would be so great as the writer of the paragraphs in question seems to think. Many people even yet take the trouble to weigh their pyro, but even if they do not the substitution of four grains for three would not have a very alarming effect, even in the hands of a "beginner."

The leading article a week or two since on *The Effect of Reversing Landscape Lenses* is one that provides a very useful hint to many young amateurs who possess only one lens for all purposes, and that a single one. How to use it to the best advantage for portraits is the question, and as few amateurs, owing to the absence of accessories and the usual conventional "fixings" of a full-length portrait, ever care to go beyond vignette busts, the employment of the single lens in the manner described, *i.e.*, convex side to the object, and stop between lens and plate, will generally give a better result both as regards sharpness and rapidity. Of course, for a full or three-quarter

length the lens should be used in the ordinary manner, and with a comparatively small stop. For mere busts a stop of $f/6$, or even larger, will answer if the lens be a fairly good one.

Appropos of this question of makeshift lenses, I some years ago heard an old and presumably experienced photographer affirm and strenuously maintain that for portrait purposes, where a long-focussed objective was required, the *back* combination of a portrait lens gave a better result than the front similarly employed. I could not at the time recognise the probability of this, and I must say that a subsequent trial with the components of the only portrait lens I could put my hand on at the time utterly failed to corroborate the claims. While the idea is moving in my head, therefore, I should like to again raise the question in the hope that some optical authority may tell us the truth of it. If it really be the case the thing is worth knowing.

When a case reaches the House of Lords it is usually considered to have reached the Court of Final Appeal—to have, in fact, arrived at finality. In the case of photographic plates and the Custom House, however, things appear to have commenced at the wrong end. One day last week—I cannot find my “evening paper” to refer to it—a noble lord asked a question on the subject of the difficulties experienced by amateur photographers in passing their plates through the various Custom Houses, notably our own. The speaker instanced the case of a friend of his, who, returning from a tour on the Continent, experienced no difficulty until he reached Plymouth, where, in spite of his protestations, the authorities insisted on examining his undeveloped plates—not that they suspected anything contraband, but because being pictures they might be indecent, and therefore unfit to be passed. No dark room being immediately available the traveller was detained for twenty-four hours, during which he managed to have the plates developed, when “the most indecent picture discovered was a picnic party on the edge of a crater!”

So much for the sort of annoyance met with. Lord Salisbury's reply was as vaguely encouraging as such replies usually are. He supposed he ought to support the Customs officials, and proceeded to do so by saying that this hard-worked class of individuals could scarcely be expected to be walking encyclopaedias of science, but, having said so much, he was fain to confess that in this particular instance the officials had acted with unwonted stupidity, and that now the matter had been mentioned, *perhaps* something would be done. That is, briefly, my recollection of the newspaper report; and now the matter has been raised “in the Lords,” let us devoutly hope, with the Prime Minister, that something will be done soon and effectually.

I notice in last week's JOURNAL my colleague, “Free Lance,” alluding to the use of “gun-cotton,” “gun-paper,” and “gun-sawdust,” speaks of the first and last as being likely to excel papyroxyline in rapidity of flash. That is quite my view held from the first, and now confirmed by experiment; the closeness of texture of the papyroxyline causes it to burn slowly, but at the same time we must remember, as Longfellow says,—

“Though the mills of God grind slowly,
Yet they grind exceeding small;”

or, as Herbert put it at a much earlier date, “God's mill grinds slow, but sure.” So the slow burning and the intense heat of the thick close paper ensure the complete oxidation of the magnesium, instead of blowing much of it away unchanged, as is invariably the case with gun-cotton. No doubt the prepared sawdust would form a nearer approach to rapidity and efficiency combined, but my recommendation of papyroxyline was, if I remember rightly, made in connexion with time exposures, not for sudden flashes.

I get some singular information from the column of “Foreign Notes and News” at times. For instance, I find that “a correspondent of *L'Amateur Photographe*” had the misfortune to get nervous over the water he was obliged to use when travelling, and which, from its hardness, he did not think would agree with his ferrous oxalate developer, so he set to work to boil it three separate times with a portion of his ferrous oxalate—that reads like sufficient to precipitate a whole kiln full of lime—though only a litre of water was operated upon, carefully filtering each time, and, at the finish, he had some water which, “though not pure, allowed him to develop his negative.”

I very seldom use ferrous oxalate myself, but if I did so, and were

placed in the same circumstances as this truly smart “correspondent of *L'Amateur Photographe*,” I should economise my developing solution, and not waste unnecessary time in boiling and filtering a few ounces of water. Commencing with water as I found it, “though not pure,” I would trust to its allowing me to develop my negatives, and if, after my return home, or to the regions of purity, any signs of lime appeared on the negatives, I would submit them to a weak bath of hydrochloric acid. The plan, perhaps, does not sound so well nor so scientific as the foreign one, but I think it would answer.

Then again, “Dr. Stolze indicates the following as the best means of modifying a landscape negative.” Then follows a description of the application of the “dusting-on” process to the back of the negative. Oh, Mr. Werge! how many years is it since you first described that method? and how many photographers are there in this country who have aspired to journalistic fame who would think of now putting it forward as a novelty? But, perhaps, the *Wochenblatt* wants filling, and it is hard work. But the compiler of the *Notes* need scarcely repeat such old stuff for the benefit of English readers!

JUNUS.

PAPYROXYLINE FOR FLASH-LIGHT PURPOSES.

I HAVE not noticed until the matter was briefly alluded to by “Free Lance” last week that any comments have been passed upon the proposal to substitute papyroxyline for ordinary pyroxyline in the combustion of magnesium powder for photographic purposes. Undoubtedly at first sight an inflammable or explosive material in the form of a continuous sheet seems to offer palpable advantages over such a disconnected material as unwoven cotton; but I think, when the subject is examined more closely, other elements will be found to operate in a contrary direction.

The suggestion of “Free Lance,” for instance, with regard to the greater supply of oxygen available in the case of ordinary gun-cotton, has one important bearing upon the “flash-light” question, since it materially affects the rapidity of combustion; but that the outward supply of oxygen is necessary for the purpose of explosion is negated by the fact that the explosive force increases as the material is shut off from outward influences. In fact, in the discussion that has already appeared on the subject, combustion and explosion have been taken as synonymous, whereas they are totally distinct.

For instance, it was suggested as an objection to Mr. A. L. Henderson's proposal to dissolve pyroxyline, and having incorporated it with magnesium powder and chlorate of potash to work it into sheets, that the most explosive kinds of gun-cotton are quite insoluble. Then it was proposed, by “Junius,” I believe, to form such sheets by cementing magnesium powder between two separate sheets of papyroxyline of the highest explosive power in order to secure rapid and perfect combustion; but in both cases I think the mistake is made of assuming that high explosive power is synonymous with, or accompanied by, quick combustion in the absence of pressure. My own recollection of occasional experiments with different kinds of gun-cotton, spread over many years past and including some made quite recently for this purpose, induces me to say that there is not the least connexion between the two, or that, if there be a difference, it is generally in favour of rapidity of combustion of the *least* explosive kinds. Theory, too, would seem to point, if not to the absence of any rule on the point, at least to the fact that the chemical changes that go on during explosion and combustion respectively are materially different, and therefore that the processes are different.

The controversy was commenced, as I have said, by Mr. Henderson's proposal to incorporate magnesium and chlorate of potash with pyroxyline in the form of celluloid; but an objection was raised against this on the score of its probable slowness of combustion. We all know how difficult it is to burn celluloid in the mass, and also that even when in extremely thin sheets, as in the waterproof collars and cuffs now sold, it only burns slowly like paper if a light be put to it. But it seems to have been forgotten that the presence of chlorate of potash in Mr. Henderson's compound, by supplying the oxygen needed for combustion, and by the consequent increase of temperature, would vastly increase, not only the rapidity, but also the intensity of the combustion of the material, which without it would, perhaps, be but slowly inflammable.

Turning to the proposition of "Junius" to employ highly explosive papyroxyline, I cannot see that matters are at all improved unless precisely similar measures to those of Mr. Henderson are adopted, namely, the incorporation of chlorate of potash as well as magnesium with the compound sheets. As "Free Lance" points out, the atmosphere, and therefore oxygen, has fuller and freer access to pyroxyline in its ordinary form than it can possibly have in the case of papyroxyline, the close texture of which tends to explosiveness and intensity rather than to rapidity of combustion. For the perfect consumption of the metal without scattering it in the unburnt state, no doubt papyroxyline would be superior to guncotton, and where a slow exposure, not a flash, was required, most likely the former would get more light out of a given weight of metal simply because it wastes none. But for "flash" exposures I imagine guncotton must remain supreme.

I have recently been amusing myself by making various kinds of explosive guncotton, or, rather, I should perhaps put it, guncotton of various degrees of explosiveness, from different materials, and a brief *résumé* of one or two such experiments purposely made will go further than much theory to clear up the question. It is well known that paper or any manufactured material requires a far longer immersion in the mixed acids than is the case with raw cotton, in order that the fibres may be thoroughly acted upon, and that for explosive purposes the acids employed must be in their most concentrated form in order to secure the highest degree of nitration. It follows merely as a working detail that the temperature of the acids should be kept as low as possible in order to prevent solution of the material.

The strongest commercial sulphuric and nitric acids of s.g. 1.45 were mixed in equal volumes, and, when quite cold, as much thin unsized paper, cut in small sheets, as the liquid would well cover was pressed in with a glass rod and left for twelve hours. It was then pressed, drained, and well washed, being finished with very weak ammonia, and dried. The result was a thick, tough papyroxyline, resembling stout parchment paper in appearance and practically quite insoluble in equal parts of ether and alcohol, though it swelled and became semi-transparent after long soaking. It burnt almost completely, leaving but a faint trace of ash, but so slowly, as compared with another sample of papyroxyline made for photographic purposes with more dilute acids and higher temperature, that I should estimate the relative rates of combustion at about six to one. This difference was undoubtedly due to the closer and denser character of the explosive compound, due to the parchmentsing action of the concentrated sulphuric acid, the photographic sample being far more open and pulverulent in texture.

Another experiment consisted in treating a quantity of soft lamp wick, and in this case I adopted Von Lenk's method in its entirety. This consists in an immersion of the perfectly dry cellulose in the mixed concentrated acids for a period of twenty-four hours, after which it is transferred for a similar period to a fresh quantity of unexhausted acid. In this manner the very highest degree of explosiveness is obtained. Lamp wick so treated, thoroughly washed and dried, burnt so slowly that a piece an inch long occupied two or three seconds in combustion, but underwent perfect consumption, as scarcely an atom of ash remained. The colour of the flame was intensely yellow, far more so than is usually the case with guncotton of only moderate explosiveness. The colour, however, I am inclined to believe, is entirely due to the slowness of combustion, or, in other words, to the insufficient supply of oxygen. I say this not merely because the more open guncotton burns more rapidly and with a white flame, presumably in consequence of its freer contact with the atmosphere, but because of the closer texture. Lamp wick being impregnated with chlorate of potash, its flame becomes considerably whiter and its combustion much more rapid. But it is possible that the colour may be due to quite a different though still not unconnected cause.

Pyroxyline—of whatever form—differs from gunpowder in that its products of combustion are, with the exception of faint traces of carbon and of ash, wholly gaseous, amongst the compounds formed being nitric oxide, which in combustion with an additional atom of oxygen forms the "nitrous fumes" given off by nitric acid when acting on certain substances. Clearly the higher the degree of nitration of the pyroxyline the larger the proportion of nitric oxide

formed, and if this possess any calorific action on the flame, we have a possible explanation of the yellow colour in this case.

I may mention a curious circumstance bearing upon the difference between combustion and explosion. Of course, it is well known that the same guncotton that burns harmlessly in the open air explodes with violence when ignited in a confined space or under pressure. I have already pointed out that whereas free oxygen is necessary for rapid combustion, its absence promotes explosion. But if the final products of combustion and explosion respectively be examined, it will be found that in the latter case the nitric oxide is altogether absent, its oxygen having been separated from it entirely, and the whole of the nitrogen left in the free state. According to the experiments of Lieutenant Karolyi, of the Austrian Artillery, it appears that whereas the products of combustion of tri-nitro-cellulose *in vacuo* contain about ten per cent. by weight of nitric oxide, the same when exploded under a pressure just sufficient to give way under the force of the explosion shows no trace of nitric oxide, but larger quantities of carbonic oxide and carbonic acid, as well as aqueous vapour. It may, therefore, be looked upon as more perfect combustion, brought about, no doubt, by the vastly higher temperature.

This circumstance also explains what was to me for long a mystery, namely, the fact that whereas in burning guncotton in the open you can *smell* the nitric oxide, yet in employing it for military or sporting purposes it is noted not only for its non-fouling, but also shows no tendency to corrode the gun, as might be expected. But under the circumstances, as will be seen, no corrosive fumes are formed.

I may say just one word with regard to the employment of gunpowder in conjunction with magnesium in contrast with pyroxyline. The products of combustion of the latter, as I have said, are practically all gaseous; but in the case of powder no less than *two-thirds* of the products are solid, and amongst the gaseous portions will be found such delectable combinations as sulphuretted hydrogen. Surely there is little inducement to adopt this plan!

In conclusion, I may mention a method that I have found both useful and easy, by which papyroxyline or guncotton can be evenly impregnated with finely-pulverised chlorate of potash. This salt, it is well known, is very slightly soluble in cold but freely in hot water. Make a boiling or, at any rate, hot saturated solution, and dip the cotton or paper in it, and press out the surplus liquid; on cooling, the excess of chlorate will be deposited in very fine powder. The same process answers admirably for powdering this awkward salt. Dissolve it in just sufficient water by boiling, and as it cools the salt will fall down in the finest powder.

On the whole, though papyroxyline may answer for slow exposures, I do not think it will prove of much use for "flash" work.

W. B. BOLTON.

COPYING PAINTINGS AND WORKS OF ART.

II.—AWAY FROM THE STUDIO.

POSSIBLY the most graphic way in which to put the difficulties and troubles of successfully copying old oil paintings will be to give illustrative cases and the methods adopted to overcome them. This may be better than a more didactic exposition, and thus enabling the details of careful work and manipulation to be stated, and rendered less dry and uninteresting than if a mere set of instructions and formulæ were duly set down, even when they are stated in the simplest way, as it is not given to every one to read through imperfectly-stated methods and baby fashions of imparting information, which does not always do, even although accompanied by common sense on both sides.

Some five-and-twenty years ago I was called upon to photograph the entire set of historical pictures, documents, and other interesting material connected with a now dormant peerage, the titles and greater portion of the estates connected therewith having been estreated in consequence of the share taken by them in the Stuart rising of 1715 and 1745. The then holders of the titles were Jacobites of the most extreme type, and after these two abortive rebellions sunk into comparative obscurity, some of the family losing their lives and liberty, as well as their goods, estates, and chattels. This necessitated prolonged visits to the family mansions of a number of the old Jacobite nobility and gentry, and some of the experiences may be related, bearing, as they do, on this subject, and elucidating it as well. The copies of the pictures, which were principally portraits, were to be executed to suit the pages of a privately-printed

history of the family. When it is considered that these pictures were of all dimensions—some of them being life size, full length, say eight feet by five, others half lengths, and so on down to enamels; miniatures on ivory, one of the latter being so small as to be used as the decoration of a finger ring; others were marble busts and figures, monumental memorials, and such-like works of art; views of the castles and mansions connected with the family, as well as MS. monuments and such-like—it will be seen that, while one camera of the proper description might suit the work, the same could not be said of the lenses, for experience proved that it required quite a battery of them, and those of the best kinds then available or obtainable. As this is practically a record of experience, and as we all learn by that Rhadamanthine monitor, at least all who are capable of learning, details will be useful, if not also interesting.

The camera determined on was a square one, capable of holding plates $8\frac{1}{2} \times 8\frac{1}{2}$, or, as then used in practice, and called full plates, $8\frac{1}{2} \times 6\frac{1}{2}$, either upright or oblong, as the subject required. This form of camera is decidedly more convenient than one needing to be altered in either direction, as the subject might demand, and it saves a lot of bother, time, and trouble. It was none of your gimcrack pieces of workmanship, but consisted of a good solid sliding box, not made even for portability, that being in this case the last requisite, but having, in addition, a bellows arrangement inside, and with a folding baseboard, making the camera capable of elongation up to nearly three feet; this, with separate fronts for the lenses, and with the necessary different movements, made one of the most perfect tools I have yet made and used for photographic purposes at home or abroad.

The lenses were the best rectilinears of the period—triplets—doublets for that purpose being not yet; there were also one or two of each of the ordinary landscape and portrait classes taken, which, if not capable of reproducing absolute rectilinearity, were still thoroughly fitted for some kinds of copying and for many other purposes.

The stand was a tripod one, made specially rigid, much like that of a theodolite, which, while being sufficiently portable, was not too heavy, and the tripod head was made exceptionally large, extending as it did to the outside edge of the camera's width, the extra strong legs ensuring great stability in use. In actual work it was used as seldom as possible, preference being given, where that could be got, to a firm, steady table from the hall or kitchen, the necessary adjustments for height being easily managed, either with the object to be copied or by assisting the height of the camera where that was needed. The other necessities included a store box to hold all the other things, such as chemicals—in fact, an entire workshop of all that was likely to be wanted; and be sure that a hammer, some nails, a bit of cord, and such-like, were not forgotten. The plate box, which it also held, was constructed for eighteen plates, each pair being placed back to back in one division, supplied with india-rubber tubing above and below to prevent shaking. With this precaution I have never had a broken plate. The water-tight bath was packed between this box and the inner end of the camera, and the lenses, covered up in cloths and chamois leather, packed inside the camera itself, made a neat package about twenty inches long, thirteen high, and a foot wide, or thereabouts, which when wrapped up in a large black baize cloth, the use of which has been explained, made a neat, tidy package, neither too bulky or too heavy. This outfit is as good now for use in dry-plate work as it was at first for the wet, the space got by the discarding of the bath being occupied by a couple of double dry slides and trays, and for dry-plate work away from the studio is as perfect and handy as it then proved itself.

One of the first places to be visited in this connexion was the home of an aged countess in her own right, the last of her race, the vicissitudes of war and other such incidents having wiped out every representative of the family save herself. She was then over ninety years of age, and it was a perfect treat to see the very little old lady in the costume of her youth, even to the natty high red heels of her tiny boots, being led down for exercise, which she took every decent day. She was not afraid of a bit of a shower, and the little carriage always used was an open one. She and it made a perfect picture, with the ivy-clad walls of the old border fortress, as they stood on the terrace in front of the main entrance to the castle; this terrace had evidently been added as an afterthought in less warlike times than that in which it had been first built, to get more easily up to the then only principal entrance, which had originally been on what we would call the first or living floor of the building. This was the almost universal method of construction of the Scottish border castles and keeps in the Middle Ages, necessitated by the continual raids and forays between the two countries—Scotland and England—whose people now dwell in peace and amity, and only strive as brethren do to see who can do the best for all.

A detective camera of the present day and rapid plates would have been invaluable for securing a representation of such a relic of the past

as was then before us. The good old lady was approached and requested to allow herself to be taken by the (to her) new method of portraiture, and as I was there it would be little trouble to either her ladyship or me to do this while I was copying the portraits of her progenitors and predecessors, but she refused consent in her own stately fashion to be handed down in "that new-fangled way" to posterity.

These old portraits had been hanging in a cold and, I believe, somewhat damp gallery, and they had evidently received very slight care or attention from the time they had been painted and hung up there, the canvasses of most of them being flabby and flapping, the paint cracked, and the varnishes oxidised, dull, and dirty, except in the case of two favourites of the elderly housekeeper. They were that of a lady and a gentleman, which she had carefully cleaned and rubbed up with furniture-oil or polish, of her own make, once or so a year. These could certainly be seen better than the others, but, between the rubbing and the polish, when those two come to be put in order, they will be worse to clean and be found to be more damaged than the others, and they were bad—but that is by the way. For the purpose of photographing they were much the most suitable, requiring not the slightest use of temporary or other varnish to bring out any detail they had. That pair of portraits were naturally taken first, and proved sufficiently successful for the purpose, but when the others came to be tried they, from the causes mentioned, proved failures or comparative failures. This was not only explained to her ladyship, but prints were shown her from the different negatives with the most lucid possible explanations, but no! "They must be taken as they are while I am here, after I am gone you may do what you will with them," was all the answer that could be got. The prints were forwarded to headquarters with the remarks of her ladyship, and the result was that impressions on plain paper were taken and the details sketched in so as to enable the copies to be made from them as being the only pictures known of the historical persons represented. Fortunately, these portraits were not fine as pictures, and were only similitudes more or less correct of the persons represented, and so their deterioration, or even destruction, as works of art, was of little consequence to the world at large. Coleridge puts it in one of his dreamy, poetical visions:—

"Their bodies are dust,
Their good swords are rust,
Their souls are with the saints, we trust."

So their delineations may be left to decay, or they may be revived if another of those once noble families decides upon their preservation when they change possessors.

The photographic lesson to be deduced from this may easily be deduced. Had full liberty been allowed in the circumstances, so that good or the best photographs from these pictures must be got, this would have been the mode of procedure:—After being taken from the walls, they would have been carefully and thoroughly dusted after being removed from the frames, then washed as has been described, and after being thoroughly dried, they would have been treated to a good rubbing with the hardest kind of oil before indicated, say colza or olive, both of which are always to be had in country houses, care being taken that little or none be left on the surface, after which they would be thoroughly rubbed with a coat of Robertson's medium, or a similar material, which was always carried in the store box, but leaving little or comparatively nothing on the picture. This treatment would have allowed all the detail to be copied, not only without injury to the pictures, but with positive benefit as to their preservation. It may be asked if I would recommend every photographer to do this, either while or previous to copying dilapidated old paintings. Most decidedly no. Let this be done by a competent person who understands the work, and on whom the responsibility (if any) would rest for doing it properly. This would allow the full attention of the photographer to be devoted to his work of copying, and so allow of the best results being achieved without the chance of him being blamed for any imaginary injury the works might receive, which he might be for maddling with work that he did not understand.

W. H. DAVIES.

PROPOSED PHOTOGRAPHIC TRADE SECTION OF THE LONDON CHAMBER OF COMMERCE.

THE London Chamber of Commerce is organizing a Photographic and allied Trades Section, to be added to the various other Trade Associations which are doing so much to increase the usefulness of the Chamber. There are many scientific societies and clubs in connexion with photography, but no commercial association of the trade exists, or has ever been attempted, and it is quite time that we had a combination similar to those possessed by most other trades. We are glad, therefore, to know that energetic steps are now being taken in this direction, and

that the movement has already received the support of several of our leading firms.

There are many questions which affect the interests of the trade calling for prompt attention, such as the working of the Merchandise Marks Act, the steps which are being taken to establish the use of the decimal system in weights and measures, the promoting or supporting any application to Parliament which may be beneficial or necessary to protect photographic interests, the organization of annual exhibitions, the amendment of the Copyright Act and Patent Laws, the railway rates question, &c., besides other similar matters which may arise from time to time in the future, and which could be more effectually dealt with by an association allied with so powerful and representative a body as the London Chamber of Commerce, consisting of about three thousand mercantile firms and others engaged or interested in trade and commerce, including some forty Members of Parliament.

The Photographic Section would form its own governing body, without interference from any other branches of the Chamber, the Chairman having a seat at the Council Board, where he would represent the interests of the trade, and in case any important question should arise, the influence of the Chamber would, with the consent of the Council, be exercised upon Government Departments, including the Foreign Office and Board of Trade, upon Colonial Governments, and upon Parliament.

The help of so influential a Chamber would be of enormous utility, as it is in touch with every Chamber of Commerce in the world, and a united trade, whose members would meet from time to time to debate trade questions in a business-like spirit, and to recommend certain lines of action to a strong body, such as the London Chamber of Commerce undoubtedly is, would be able to speak with an authority almost impossible under any other conditions.

Properly supported and conducted, it seems likely that the proposed Photographic Section can hardly fail to do a great, and useful, and, we may add, much needed work, we therefore heartily wish it every success.—*Contributed.*

PHOTO-MICROGRAPHY.*

To explain to you the importance and advantage of the immersion system over the system of dry fronts, I must refer to one of the simplest and most important laws in optics, namely, that of the total internal reflection of a ray of light in a transparent medium, such as crown glass, when the angle of incidence exceeds 41° . Hence no cone of light greater than twice 41° , or 82° , can pass from glass into air but by interpolating a medium of higher refractive power than air between the cover glass of an object mounted in balsam and the front lens of an objective. We not only enable rays of any degree of obliquity to pass through the object into the objective, but the obliquity of these rays in the denser media than air—that is, in the immersion fluids—becomes less than before. In consequence of this refraction or contraction of the illuminating cone in the immersion fluid, rays of the greatest obliquity are enabled to enter the front lens and help to form the microscopical image, which rays, without the intervention of the immersion fluid, would be completely lost. Now it is obvious that the angular aperture of an immersion lens (measured in balsam) is equivalent to a far larger angle of an air lens. Professor Abbé, of Jena, has formulated an exceedingly simple expression, which enables us to compare the apertures of dry and immersion lenses, and he has called this the *numerical aperture*, viz.:—

$$a = n, \sin u,$$

n standing for the refractive index of the immersion fluid, which is for air 1.00, for water 1.33, and for a homogeneous immersion fluid, such as cedarwood oil, 1.52, whilst $\sin u$ is the sine (a trigonometrical function) of the semi-angular aperture of the lens, $2u$ being the total angular aperture. The resolving power of an objective does not only depend upon its numerical aperture, but also upon the wave-length of the light used for illuminating the object. It is greater for monochromatic blue light, for the line F of the spectrum, than it is for white light, but it is greatest for the line H of the spectrum, or for that end of it where its actinic power dwells. A homogeneous immersion objective of 180° in oil is capable of resolving theoretically per inch—

	146,543 lines by white light,
	158,845 „ by blue light,
and	193,037 „ on the photographic plate.

Here we have in figures an expression of the far greater sensitiveness to light of the photographic plate than of the human eye. In other words, we may expect that a photo-micrographic negative may reveal to us one-fourth more than the human eye is capable of seeing in the microscope. The visibility of small isolated objects must not be confounded with the visibility of fine gratings, bands of lines, or other closely approximated structure, because only in these latter appear the phenomena of interference of the diffraction spectra produced by the passage of the light through narrow interstices. To render such structure visible in the microscope, or to resolve it, our objective must have sufficient aperture, so that at least one of the diffraction spectra of the first order is collected by it. This is not the place nor the time to enter

* Continued from page 353.

into the theory of micro-objectives, but I must not omit to mention that medium and high powers, with the exception of homogeneous immersion lenses of some makers, are provided with an arrangement called a screw collar, which enables us to approximate or separate the front lens from the posterior combinations in order to neutralise the influence of different thicknesses of cover glass. So sensitive are fine wide-angled objectives, that a difference in the thickness of $\frac{1}{1000}$ inch of the little glass which covers the object may prejudicially affect the performance of the lens unless this difference can be neutralised by the adjustment of said screw collar. By far the best lenses for photo-micrography, as well as for every other purpose, are the new apochromatic lenses of Carl Zeiss in Jena, and also those of Powell and Lealand in London, which they make of the new optical Jena glasses. Several English and foreign opticians call their lenses also apochromatics, because they employ these new glasses for their objectives. The apochromatic lenses differ from the ordinary achromatic lenses, which are not strictly achromatic, as they are only corrected for two colours of the spectrum, by their being corrected for three colours, which render them practically quite achromatic. The chemical and visual foci of these new apochromatic lenses coincide, their definition and resolving power exceeds that of the ordinary achromatic lenses in consequence of the perfection of their corrections, they give a far greater amount of light and stand a far larger amplification by eyepiece than the ordinary lenses, and are, therefore, in every respect the best objectives for photo-micrography and all other microscopical work. As no good music can be got out of inferior musical instruments which are out of tune, so likewise is it impossible to obtain correct and critical images from lenses whose aberrations are not perfectly corrected.

The compound microscope consists of objective and eyepiece. The eyepiece or ocular is of the utmost importance, and if inferior in quality may ruin the performance of the best objective. The usual form of eyepiece is the Huyghenian or negative one, besides which we have the Kellner eyepiece, the Ramsden or positive eyepiece (which is almost only used as a micrometer eyepiece), the achromatic ocular, and the new compensating eyepieces of Carl Zeiss, which are specially constructed for his apochromatic objectives. These compensating oculars give splendid definition and improve the performance of other objectives as well as of that of the apochromatics. They magnify the image projected into them by the objective up to twenty-seven times diametrically. Professor Abbé has devised special projection eyepieces for photographic purposes and for the lantern microscope, and they give, perhaps, the finest definition of any eyepiece made, but their field is much smaller than that of the Huyghenian and other oculars. Besides projection eyepieces, ordinary concave amplifiers, such as those I have here, which were made by Rosa and Co., will be found very useful, as they absorb but little light, give a large field, and do not impair the definition of the objective to any appreciable and noticeable extent. The question is often asked, and seldom satisfactorily answered, whether the eyepiece should be used or not when photographing with the microscope. Well, I think the answer depends entirely upon circumstances, such as the size of the image we wish to project, the length of the camera at our disposal, and the objective we intend to employ. Should this latter give us a flat, well-defined image on the screen, and should our camera be sufficiently long to obtain the requisite size of the image without an eyepiece, then it would obviously be superfluous to employ one, as it would only absorb a quantity of light, and, unless of the best construction, would impair the performance of the objective. If, on the other hand, the performance on the screen of an objective should be improved by an eyepiece—for example, by a compensation or Abbé's projection ocular, and if we should wish to obtain a higher amplification than we can obtain by the use of the bellows alone—then we must use an eyepiece or an amplifier, but it is always advisable to use one of long focus. It is a popular fallacy to suppose that the Huyghenian eyepiece improves the flatness of the field. When photographing with the objective alone we find a practical application of the law of conjugate foci of lenses. The further we draw out the bellows of our camera, i.e., the further we remove the posterior focus of our objective, the nearer we have to focus the objective on our object, or the more do we reduce the working distance which, with high powers, may ultimately result in the working distance being so far reduced that the objective does not work any more through the cover glass of the object, thus imposing a limit upon the amplification on the screen.

The question next to be considered is that of the light to be used in photo-micrography. By far the best light, at least for high powers, large amplifications, and for shutter exposures, is sunlight, owing to its great intensity, its great actinic power, and to the parallelism of its rays. By its aid we are enabled to see some of the finest structural detail which the microscope is able to reveal. Sunlight cannot easily be used direct, owing to the earth's rotation. To ensure the falling of the sun's rays on our microscope constantly from the same direction we must receive them first on the reflecting mirror of a heliostat, which is a clock-work arrangement moving a spindle set parallel to the earth's axis or at angle with the horizon equal to the latitude of the place. This spindle carries the reflecting mirror once round its axis in twenty-four hours. A second mirror is often interpolated, but these mirrors must be perfect planes, else the parallelism of the sun's rays will be destroyed. Unfortunately the sun is not often to be depended upon, and the photo-micrographer has to press humbler luminaries into his service. The light next to the sun, as far as its actinic power is concerned, is the magnesium

light; but the lamp for the successful employment of this excellent photographic, and now cheap, light has still to be constructed. The points to be attained are not only a steady combustion of the magnesium ribbon, but also that provision should be made for collecting every particle of calcined magnesia, so that none can settle on the object and on the front lens of the objective, as in this case the enlarged images of such particles will be photographed along with the object. A few inches of magnesium wire slowly pushed through a brass tube hammered flat will suffice to give a vigorous negative when the object is magnified several hundred diameters. The electric light is rich in actinic rays, but has, on the whole, not found much favour with microscopists, for the arc light is troublesome, expensive, unsteady, and gives off a great deal of heat. The incandescent light is far more suitable and handy, but as the first principle of microscopical illumination is to project a sharp image of the source of light in the plane of the object, the image of the thin glowing carbon film, if projected by a substage condenser of short focus, becomes often too small to cover the object. The power of the battery, if one is used, must be sufficient to render the film of the lamp glowing quite white, for if this is not the case we may get abundance of red light on the focussing screen, but not sufficiently rich in actinic power to get an image on our sensitive plate, as I found once to my great disappointment. As even the incandescent electric light is troublesome to generate, unless by a small dynamo driven by power, it has, from this reason and from the one mentioned before, not made much headway in photo-micrography.

The oxyhydrogen light has been made much use of of late in photo-micrographic work, notably by Professor Crookshanks. This light is exceedingly steady and intense, and since oxygen is being supplied commercially in a compressed state in steel cylinders, its advantages over some of the sources of light mentioned are obvious, although the lime-light, as it is commonly called, possesses relatively less actinic power than either the magnesium or the electric light. The limelight is especially useful for photographing *bacteria*, for which nothing but a central cone of light is required.

The last available source of photographic light is a good paraffin lamp, and in it we have an excellent, manageable, and cheap light, which is always at our disposal, and which suffices for photographing objects under magnifications of from 400 to 500 diameters, so that we can even photograph with high powers by lamplight. All, then, that is required is a good microscope lamp, having one flat wick, of which we can employ either the edge or the broad side, as circumstances require. The lamp must be adjustable in a vertical direction, and the flame should be enclosed in a metal chimney, having a window on one side, or the glass chimney should be surrounded by a porcelain shade having an opening on one side. I line my copper chimney with plaster of Paris, so that it reflects as much white light as possible through its window, which is filled out with a disc of light blue glass. Nearly all my photographs were taken by lamplight. Any ordinary paraffin lamp costing about one shilling can be made to do excellent service in photo-micrography. It is essential that the very best paraffin oil, such as crystal oil, be burned in microscope lamps, especially when used for photographic work. Inferior paraffin oils possess elements of danger, especially when burned in lamps having metal chimneys, as these latter get very hot. Gaslight is not suitable for our purpose, as it possesses too little actinic power, and is not steady enough.

Having briefly described the microscopical part of the apparatus, we will turn our attention to the camera. The number and variety of cameras used for photo-micrography is so great that I could not describe to you this evening even all the best-known forms. Almost every microscopist arranges his photographic apparatus to suit his work and as his circumstances permit it. The smallest cameras are generally carried at the ends of the microscope bodies, which arrangement has the advantage that the apparatus can be used both in a vertical and in a horizontal position; but, as a rule, such a combination is not very steady unless the camera is either very small, or is supported by a separate stand, such as Reichert's in Vienna, which consists of a heavy horseshoe foot provided with three levelling screws, carrying a stout iron pillar, on which a frame supporting the screen end of a small bellows camera can be adjusted in a vertical direction and fixed. There are a number of arrangements for dispensing with a microscope stand altogether; in these, a stage for the support of the object and the objective are attached to the front of the camera, but they are evidently only suitable for low-power work, and if provided with stage motions, fine adjustment for focussing, &c., will be as expensive as a separate good and cheap microscope and a camera. I have seen a picture of such an apparatus of American manufacture, which had a powerful large paraffin lamp with three wicks attached to it. This is both theoretically and practically wrong, for we would project three images of flames parallel to each other on the object were a substage condenser employed for the illumination of the latter. The smaller the flame, the more have we command over the passage of its rays. Besides, a large lamp, especially if provided with three wicks, produces so much heat that the objective and the object may be ruined by it. The exposures under low powers by lamplight are quite short enough even with a small flame.

Coming to some of the best arrangements, and those which are suitable for the highest powers, those of Dr. Maddox and of Dr. Colonel Woodward, whose work has not been surpassed, deserve mentioning. These

gentlemen dispensed with the bellows camera altogether by darkening the room they wrought in completely, and allowing the sun's rays to fall only through a small hole in the window shutter after it had been reflected from a heliostat placed on a shelf outside the window. The microscopical image was projected by the objective and a concave amplifier on a screen or on an easel similar to those used for enlarging on bromide paper, and this easel moved on rails. Seated by the side of the microscope and whilst controlling its adjustments, the image was viewed by means of a powerful short-focus telescope or field glass. The image having been focussed sharply on a piece of white card, the latter was exchanged for a sensitised plate and the necessary exposure given to it.

The arrangement, which seems to meet nearly all requirements for photographing with any kind of light and with any microscopical objective, is the recent one of Dr. Roderich Zeiss in Jena, a son of the famous optician, Dr. Carl Zeiss, recently deceased. Dr. Roderich Zeiss is probably the most favourably placed photo-micrographer living, and it must be admitted that he has made excellent use of his unique opportunities. He has all the vast resources of his establishment and of the optical glass works in Jena, and the great knowledge of microscopical optics of Professor Ernst Abbe at his service, besides being himself an excellent and enthusiastic microscopist and photographer. Dr. Zeiss works in an isolated and uninhabited dwelling house, in the ground floor of one of the rooms of which he has had sunk two large foundation stones. Upon one of these stones stands a firm iron tripod supporting an iron platform, which carries either the heliostat, the arc lamp, or the oil lamp, together with stands for various pieces of apparatus, such as iris-diaphragms, alum tank for filtering out the heat rays of the sun, condensing lenses, and a fine microscope specially constructed for photographic purposes. On the other larger foundation stone stands a long, square, iron table having four legs, which table supports a long bellows camera of two sections. The camera moves on rails, so that it can be either connected or disconnected with the microscope without delay. The motion of the fine focussing screw is imparted to it by means of a Hook's joint and a long rod, the end of which the observer holds in his hand whilst seated near the focussing screen. The focussing glass is attached to the screen itself by some moveable supports. Provision is also made for placing one section of the bellows in a vertical position when the microscope is placed vertically. Two iron stools, which are adjustable in a vertical direction, the one standing near the microscope and the other near the screen end of the camera, enable the operator to make all the adjustments with ease and the greatest comfort.

Before Mr. Carl Zeiss made the large apparatus just described, I devised the simpler, but almost quite as efficient, apparatus which you see before you. It has been evolved gradually as my experience in photo-micrography ripened, and whilst my stand is not in the least ornamental, it seems to me to fulfil all the requirements of the photo-micrographer, besides being portable and cheap. My photographic bench is eight feet long, sixteen inches broad, and eight and a half inches deep; one end carries a raised platform four feet long for the support of the camera, and to bring its centre in the optical axis of my large Ross' microscope stand when the body of the latter is placed horizontally. This platform, to the underside of which are glued strips of indiarubber to deaden vibrations, can be raised for the purpose of photographing with the stage of the microscope placed horizontally, in which case I employ a large rectangular prism above the cross arm of the stand in order to reflect the image in a horizontal direction in the camera. The other end of the bench supports a round table twenty-seven inches in diameter, which revolves upon its axis and serves to support the microscope, the lamp, and any other apparatus which I may require. The height of this revolving table from the ground is such that it enables me, whilst seated on a chair, to focus the object and arrange the illumination of it with the utmost comfort, previous to making the light-tight connexion of the microscope with the camera. Under the revolving table and attached to the bench are five brass screws carrying little brass discs topped with indiarubber, and by raising three of these screws the revolving motion is arrested, and the table is then firmly supported and can be levelled. Along the raised platform for the support of the camera runs a brass focussing rod supported by two short pillars on plates, which slide into dovetailed brass plates screwed to the bench. This focussing rod carries at the end, near the round table, a small grooved pulley adjustable in the direction of its axis. Over this pulley and round the wheel of the fine focussing adjustment is placed a thin elastic cord, and by these means the object can be accurately focussed whilst its image is being examined on the focussing screen. The bench itself is supported at its ends by two pairs of legs and two stretchers, which are attached to it by only two screws, which can be instantly removed either for the purpose of transport or when it is desired to place the bench on an ordinary strong table. When photographing objects in fluid, or when using immersion lenses having an inconveniently long working distance, the microscope has to be placed in a vertical position, and as my reflecting prism is not so perfect as not to impair somewhat the sharpness of the image under the highest powers, I have constructed a very simple addition to my bench, which consists of two hinged boards held perpendicularly to each other by means of a stout stretcher. The whole has to be fixed by means of two screws to the top of the platform. The camera is then fastened by means of two screws and brass stretchers to the vertical board, whilst the microscope and lamp are carried on the round turntable, which is now supported by a separate

square table only fourteen inches high. This arrangement necessitates, when the bellows are far drawn out, the use of a step ladder for viewing the image on the focussing screen, and it is in this position that the focussing rod proves itself a great convenience.

ADOLF SCHULZE, F.R.S.E., F.R.M.S.

(To be concluded.)

Foreign Notes and News.

THERE appears to subsist just at present what the Americans would call "a slight unpleasantness" between the Photographic Society of Berlin, of which Dr. Stolze is President, and the German Photographic Society, for which Dr. H. W. Vogel discharges analogous functions. The two Societies have similar objects and aspirations, and as will have been observed remarkably similar names—so similar, indeed, that many of us will probably be surprised to learn that they are really two separate institutions. Nevertheless, discord has recently cast her apple between them with deadly effect. It was recently proposed to hold a Jubilee Commemoration Exhibition in Berlin. Both societies appear to have indicated their willingness to support the proposal; but as the time for taking active measures for the realisation of the common object approached, it appeared that each had determined to have its own exhibition in its own suite of rooms, and to jubilate unsocially by itself. The *deus ex machina*, in the shape of Herr von Giesler, Minister of the Interior, has been wheeled in, and he has refused to let them have their exhibition at all unless they agree to hold it together. Will Tweedledum and Tweedledee after this patch up their quarrel? A better instance of the sturdy Teutonic independence, which Prince Bismarck the other day said made the German so much harder to govern than the Frenchman, it would probably be difficult to discover.

A VERY useful form of universal lamp was recently exhibited before the Society of Friends of Photography in Berlin. It may be employed both in the studio and on excursions. When furnished with a red cylinder it can be employed in the dark chamber, and an arrangement for blowing magnesium through the flame permits of its application as a flash lamp. The case in which it is packed is so made that it may be employed as a reflector. A very excellent negative was shown taken by this lamp by the combustion of from two to three centigrammes of magnesium powder.

THE President of the above society also exhibited a number of very interesting photographs, which Herr von Delden, in Breslau, had succeeded in taking during a *bal masqué*. The photographs in question were remarkably successful, and show that as far as portraiture is concerned photography has become completely independent of daylight.

THE Russian portrait photographers have a disagreeable *penchant* for over-retouching and for printing on rose-coloured albumen paper, which they press into relief and glaze (enamel?) excessively. Some also indulge in producing ultra-Rembrandt effects, which they heighten by the assistance of coloured backgrounds and other somewhat meretricious devices. A large picture of a lady in ball toilette, behind whose charms smiles a brilliant blue sky on the one side, while they are menaced by a threatening thunder cloud on the other, may serve as an example. In the case of all the larger exhibits a great degree of positive retouching seems to have been employed, with the result that they appear more like drawings than direct photographs.

RATHER tasteful exhibits by St. Petersburg artists and dealers help to fill up and complete the exhibition. The attendance of the public, particularly of the innumerable local amateurs, has been very large, and the jury is at present going through the performance of its somewhat laborious functions.

THE Photographic Jubilee Exhibition in St. Petersburg, the preparations for which were noticed in this JOURNAL some time ago, has been recently opened. The exhibition is specially intended to commemorate the services to photography of Daguerre, Talbot, and Niepce, a subject which formed the principal theme of the speech with which the President of the St. Petersburg Photographic Society, General Timaschitschek, opened the proceedings. The general excellence of the exhibition hardly appears to have satisfied the expectations which its pretentious title, and the resources of a city like St. Petersburg, were calculated to raise; and even the choice of the site, and decoration of the rooms allotted to it, were not especially happy. Among the principal exhibitors are Stein and Hoppe (St. Petersburg), Cronenberg, (Bavaria), and the Munich Autotype

Company, as also Warnerke, whose collection was especially extensive. The firm of Anschütz was represented by a number of instantaneous photographs, among which figured the well-known impressions of storks on the wing, manœuvres, and sporting scenes. Robinson, of Tunbridge Wells, was also represented by eight *genre* pictures, executed in his usual masterly style.

PROFESSOR SALCHER, who, in conjunction with Professor Mach, was the first to photograph projectiles during their flight, and who also succeeded in obtaining impressions of the air-waves preceding and following the ball, has lately extended his experiments to taking photographic impressions of air in motion from other causes. On permitting air under a pressure of from fourteen to nineteen atmospheres to escape from a circular opening of about five c.m. diameter, a lyre-shaped figure appeared immediately in front of the opening, whose open ends extended right into the aperture from which the air was issuing, while the curved portion of the figure was cut across by another figure somewhat resembling a pair of scissors. When the pressure was less, and the air escaped through a rectangular opening, there appeared a succession of figures of the accompanying form:—(). The figures diminished in size with increasing distance from the opening. The possibility of photographing these phenomena was doubtless due to the air issuing from the opening having a different refractive index from the air around it, and consequently producing an effect upon the light transmitted through it similar to that observable by the eye above heated surfaces, or over dry ground in hot weather.

Our Editorial Table.

STEREOSCOPIC TRANSPARENCIES.

By W. I. Chadwick, Manchester.

WHAT a beautiful thing, to be sure, is a stereoscopic transparency, more especially when, as in those now before us, the technical errors which are so prevalent are entirely eliminated! Mr. Chadwick has for a considerable period made the subject of the stereoscope so peculiarly his own that we naturally look for the highest development of the art in any pictures which emanate from him, and bear the impress of his own handiwork—nor do we look in vain.

The subjects which comprise the series are mainly *Reminiscences of the Royal Jubilee Exhibition, Manchester*, although some others not entitled to rank in this category accompany them. They are all mounted with mats, and have a backing plate of finely ground glass—so finely ground, indeed, as scarcely to show any granularity—a fault, by the way, which is much too common, and which seriously detracts from the merits of otherwise fine pictures. From a conversation with Mr. Chadwick we learn that he hopes soon to minimise the residuum of any lurking granularity by a preparation which, while forming a perfect backing, shall be entirely devoid of grain, even when examined through a powerful magnifier.

In these exhibition reminiscences the lighting and general manipulation must have been cleverly managed—as, for example, in 36, in which there are a large number of white marble statues on black marble pedestals, the statues being soft and fine, and devoid of chalkiness, while the pedestals are also depicted with the necessary detail. Or, again, as when in 112 the statuary in the foreground is so subdued, without any detail being lost, as not to have interfered with the perfect rendering of the paintings which cover the walls beyond. In one of these the leading painting is the now well-known *Village Wedding*, the popularity of which, when in the exhibition, was evinced by the tangible fact that no less than four times had the carpeting in front of it to be replaced. Well, this painting and the others which surround it are as perfectly rendered as if the most approved methods of orthochromatic photography had been employed in their reproduction. This, indeed, is somewhat of a noticeable feature in all of Mr. Chadwick's interiors: the paintings are admirable in themselves, while equally so is the white marble statuary in the same photographs.

The subjects not appertaining to the exhibition embrace several attractive scenes in the picture-teeming county of Derby. In their characteristics they are quite equal to those of the exhibition.

Mr. Chadwick has adopted, and, we are glad to perceive, is manufacturing for others, an outfit having special reference to the production of stereoscopic negatives and prints, more especially transparencies, which renders the production of these charming pictures a matter of extreme facility. Both camera and slides are unique, and partake largely of the best American ideas. The camera, as will be remembered from our description of his exhibit at the Photographic Society of Great Britain, is also readily convertible into a stereoscope in which to view its own productions. He informs us that since the beginning

of this year, and notwithstanding the inclement weather that has prevailed, he has supplied no fewer than seventy such outfits, which we are very glad to learn, as it indicates a rapid growth in the taste for stereoscopic photography.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
June 3	North Middlesex Club	The Iron Room, Stroud Green.
" 3	Carlisle and County	Cathedral Hall, 57, Castle-st., Carlisle.
" 4	North London	Myddelton Hall, Upper-st., Islington.
" 4	Holmforth	
" 4	Sutton	Society's Rooms, Sutton, Surrey.
" 4	Sheffield	Masonic Hall.
" 4	Bolton Club	The Studio, Chancery-lane, Bolton.
" 5	Coventry and Midland	The Dispensary, Coventry.
" 5	Edinburgh Photo. Society	Professional Hall, 29, George-street.
" 5	Photographic Club	Anderson's Hotel, Fleet-street, E.C.
" 6	Leeds	Philosophical Hall, Leeds.
" 6	Glasgow Photo. Association	Religious Institute, 177, Buchanan-st.
" 6	London and Provincial	Masons Hall Tavern, Basinghall-st.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

MAY 28.—Mr. W. E. Debenham in the chair.

The CHAIRMAN laid before the meeting a specimen cloud negative and what was called an "opaline" print, which had been sent to the Society.

Mr. A. COWAN exhibited a negative stained yellow by quinol development, and said that he had traced the cause of the yellowness to the presence of even the smallest quantity of bromide of ammonium in the developer; bromide of potassium did not produce the yellowness. He had been unable to remove the stain by perchloride of iron or other agents.

The CHAIRMAN liked to see the causes of faults thus traced out.

Mr. LESLIE MONTEFIORE had never had yellowness with quinol, and had never tried ammonium bromide in the developer.

Mr. CHAPMAN JONES said that so far as he had seen in work brought to him by students, quinol stained worse than pyro.

Mr. LEON WARNERKE temporarily attached films to glass by means of a sticky material, which once applied to the glass seemed to last for ever; it was a compound of indiarubber and gum elemi.

Mr. A. COWAN thought that Carbutt's films were coated of such a size as to cut into four, for quarter-plates.

Mr. WARNERKE thought that there was no glycerine in the Carbutt film, and that the slight roughening of one surface was done by chemical and not by mechanical means; he supposed that the celluloid sheets were cut from a block and then submitted to heavy rolling or other pressure. About twenty years ago he (the speaker) had been in communication with the Xylonite Company about celluloid films for photographic purposes, but the sheets were too rough, and the Company had not then any fine-enough rolling machine to make them better.

Captain MANTELL (the Hon. Secretary) asked why a negative he produced had come out thin and fogged, unlike others on plates from the same batch; it had been developed by a man in his school.

The CHAIRMAN remarked that the whole film had been considerably fogged by light, and probably during long development.

Captain MANTELL stated that it took from half to three-quarters of an hour for development.

Mr. COWAN thought that great dilution of the developer and long exposure to the light of the developing room might have produced the result.

Mr. WARNERKE exhibited some photographs of the last meeting of the Council of the Photographic Society, which he had taken by the magnesium light. He also exhibited an instantaneous photograph he had taken by the magnesium light at the last meeting of the West London Photographic Society.

Captain Mantell exhibited a silver print which he had toned in the cold-bath platinum developer, and which was slightly yellow.

The CHAIRMAN remarked that it looked like a print on India tint paper. Captain MANTELL had tried to copy a blue and white line photograph by means of the camera, and could not get sufficient contrast in the results.

Mr. FRIESE GREENE recommended him to soak the blue print in bichromate of potash, which would turn it green, and render it easy to be copied.

Mr. WARNERKE preferred to use optical means for the purpose; he employed yellow glass in front of the magnesium lamp, and nothing but direct experiment would reveal the best kind of yellow glass for the purpose. He then burnt twenty-five inches of magnesium ribbon in illuminating the print from one side, and afterwards another twenty-five inches in illuminating it from the other; if the print were at all creased, the way this method of lighting would prevent the appearance of the creases in the negative was astonishing. His magnesium lamp was a good one for the purpose and bought in Berlin. The speaker added that M. Louis Duos du Haumont had recently made the curious discovery that if, instead of a pinhole, a fine slit be used as the lens, distortion of the image is the result; a vertical slit gives a different kind of distortion to that given by a horizontal slit.

Mr. CHAPMAN JONES stated that if an unexposed plate be put into the developer until the plate begins to stain, and then be washed but not fixed, dark particles will be found on the back of the film, near the glass, as if some unduly sensitive particles had settled there. Plates varied very much in the extent to which they became spotted under this treatment, and he had used the method to differentiate the plates of different makers.

Mr. J. D. ENGLAND supposed that with a coarse emulsion, which did not set rapidly, some of the coarser particles sank to the bottom and were not sufficiently protected by gelatine.

The CHAIRMAN thought that perhaps imperfect cleansing of the glass had something to do with the matter. If the other explanation were the true one, the method was an excellent one for testing the fineness of any particular emulsion and whether the film had been sufficiently quickly cooled.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

MAY 23.—Mr. A. Hadden in the chair.

The HON. SECRETARY read a letter from the Photographic Club, asking for co-operation in getting the metric system established among the photographic societies.

The CHAIRMAN said that it would be well if the members were to express their opinion respecting the desirability of introducing the metric system into their midst.

Mr. J. TRAILL TAYLOR said that sooner or later they were bound to adopt the system, and the sooner the better.

Mr. E. P. CEMBRANO explained that the metric system when once it became understood was infinitely better than that in use in this country. He was well acquainted with both methods, and invariably calculated formulae by the system of parts.

The HON. SECRETARY reminded those present that, at a meeting of the Photographic Club the previous week, Mr. Foxlee exhibited some measures graduated on one side with English and on the other with French measures. He thought the use of such measures would be at least a stopping-stone in the right direction.

Mr. W. COLES directed attention to the anomaly that in English weights and measures both eight drachms and sixteen drachms made one ounce.

It was decided by vote that all formulae laid before this Society should in future be according to the metric system or in parts.

Mr. W. H. Prestwich passed round a dark slide he had invented in which the plate was inserted from the front and held in position by a spring, necessitating only one opening in the dark slide.

Mr. ANDREW PRINGLE called attention to a stop action at certain openings in an iris diaphragm and also to a diaphragm containing a slit for holding a coloured film for use in colour-correct photography.

Mr. V. BLANCHARD was then called upon to demonstrate his new method of toning prints with platinum, a number of prints toned by this means having been exhibited at the meeting.

In the course of his introductory remarks, Mr. BLANCHARD said that fifty years ago pictures on matt-surface paper were considered the correct thing from an artistic point of view, and that after photographs with glazed surface had been in vogue for many years the public were again coming to the belief that a matt surface was more satisfactory. They were indebted in large measure to Mr. Willis for the invention of the platinum process. He called attention to the black tints of some pictures, and explained that the best black was not such a colour as would be obtained by mixing lampblack with a requisite fluid, but a black containing an admixture of colours, such as reds, in order to form a strong black purple. He considered that in producing a photograph it was quite as legitimate to print in clouds as for an artist to paint them in a landscape on canvas. His process was the result of close application and of hundreds of experiments, and, although he did not intend to inform the meeting about the composition of the solution he employed, he was quite willing to allow them all to see the *modus operandi* of his working. Exposed prints on plain paper having been submitted for examination, they were immersed for a few moments in hot water, after which they were placed in the toning solution, also made hot.

Mr. CEMBRANO asked how long the solutions would keep, and if they could be used over and over again.

Mr. BLANCHARD said they would keep indefinitely if they were strengthened as they became exhausted.

Mr. CEMBRANO: What is the result if a print is over toned?

Mr. BLANCHARD: It will become weaker.

Mr. S. G. B. WOLLASTON asked the relative cost of producing prints by this process compared with other processes of toning.

Mr. BLANCHARD: There being no waste, his process would be about twenty-five per cent. cheaper.

Mr. J. J. BRIGNSHAW inquired if heat was absolutely necessary when toning.

Mr. BLANCHARD: Not absolutely necessary, but in order to expedite the toning it is necessary.

About fourteen prints having been toned, Mr. BLANCHARD called attention

to the small quantity of toning bath that had been employed, there only being enough solution to cover the prints, which had all been immersed together.

In reply to a question by Mr. Cowan, Mr. BLANCHARD said when the prints were fixed in hypo the tone was altered imperceptibly, if at all.

The CHAIRMAN asked if the prints had been submitted to any test to try their permanence.

Mr. BLANCHARD said he had given them a prolonged soaking in hypo, and also in a weak solution of chloride of ammonia, without any change.

Mr. TAYLOR remarked that Mr. Lyonel Clark had recently written a letter on platinum toning; might he be allowed to ask if the method therein described and Mr. Blanchard's were analogous?

Mr. BLANCHARD said only in this respect, that platinum was used in both; all the other particulars were totally dissimilar to his method of procedure. He had tried the method spoken of and certainly got pleasing results.

Mr. F. A. BRIDGE: How long do you fix the prints?

Mr. BLANCHARD: For about ten minutes. He had recently been experimenting with rough, thick paper, and was, so far, delighted with his success.

Mr. WOLLASTON said he had had a good deal of experience in platino-type printing, and did not think the shadows in the samples by Mr. Blanchard's process before them were so good.

Mr. BLANCHARD observed that they were considered better when seen in a good light, his pictures having a soft, velvety appearance.

Mr. PRESTWICH asked if an albumenised print can be toned with this agency.

Mr. BLANCHARD: Yes.

The CHAIRMAN exhibited a piece of a platinum print which had been in chlorine water for six months, and also produced the part of the picture from which the sample had been taken. It would be observed that it had not undergone any change. Would Mr. Blanchard allow him to submit one of his prints to this treatment? He thought that when silver and gold were present together in a print an electrical action was set up which caused fading, and in his opinion it was the same if platinum were accompanied by another metal, but that if platinum alone were contained in the print it would last longer.

Mr. BLANCHARD thought the tests respecting permanence rather extreme. He claimed permanency for his pictures under everyday conditions rather than in soaking in chemicals which would destroy even the paper.

Mr. H. S. STARNES inquired about the yellowness with age of the whites of pictures.

Mr. TAYLOR: In one case in question on examination it was found that it was the paper, and not the picture, which had become yellow. There were certain organic salts of silver present in albumenised paper which were not amenable to hypo, requiring the addition of ammonia.

Mr. A. COWAN: When working a lens with a fixed focus for a detective camera, was it better to have it focussed for the near or the distant objects?

Mr. TAYLOR: For the distant object.

The subject for the next meeting is to be *Old Silver Prints*, the members being invited to bring such prints as they may have in their possession. Mr. Kerr in the chair.

NORTH LONDON PHOTOGRAPHIC SOCIETY.

MAY 21.—Mr. A. Mackie (Vice-President) in the chair.

The Hon. SECRETARY read a communication from the Photographic Club, recommending the adoption of the metric decimal system of weights and measures.

The CHAIRMAN opened the discussion, stating that the decimal system had every advantage over the present method; it is quite simple, and there would be no more confusion between troy and avoirdupois weights as at present, the grain being the only weight common to both.

It was unanimously decided that the excursions should be resumed for the season.

The CHAIRMAN showed a negative developed with hydroquinone, in which, after several trials, he had obtained all the good qualities of pyro without any stain. The following is the formula in the decimal system:—

Hydroquinone	20 grammes.
Sulphite of soda	15 "
Meta-bisulphate of potash	5 "
Methylated spirit	60 cubic centimetres.
Water to make 140 c.c.	
Caustic potash.....	20 grammes.
Bromide of potash.....	1 gramme.
Water to make 200 c.c.	

For use, take 1 c.c. of each to 25 c.c. of water.

On Saturday, June 1, there will be an excursion to Waltham Cross. First train after two p.m. from Liverpool-street.

The next meeting will be on June 4, when Mr. Valentine Blanchard will demonstrate his new printing process.

HOLBORN CAMERA CLUB.

MAY 24.—Lantern slides shown in Club Room by the limelight.

The following members were elected:—Messrs. Alfred E. Read, H. V. Clements, Humphreys, and G. Tomalin, jun.

June 1 will be a field day to Woodford, on the occasion of the cyclists' meet.

On June 7 Mr. E. Clifton will, at eight p.m., coat plates and show their chemical composition.

EAST DULWICH AND PECKHAM PHOTOGRAPHIC SOCIETY.

MAY 17.—Mr. L. Warnerke in the chair.

Mr. NEWMAN attended and explained to the Society his shutter, and also a new hand camera which he is bringing out.

Mr. Warnerke showed a flash lamp adapted from a common spirit stove.

He also exhibited prints from the negative taken of the members of the Society by means of the flash light at the last meeting.

Mr. Dowling exhibited a "Dubroni" camera, which, though now out of date, was a novelty to many of the members.

Ten gentlemen were elected members.

The next meeting of the Society will be held on Friday, June 7, at eight p.m., when Mr. Edwards will give a demonstration on *Platino-type*.

HACKNEY PHOTOGRAPHIC SOCIETY.

MAY 23.—Mr. J. Hubert in the chair.

Mr. E. J. WALL read a paper, *Defects in Negatives*.

On June 13, Mr. Hubert will read a paper on *Platino-type*.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

MAY 23.—Mr. B. Karleese (Vice-President) in the chair.

A letter was read from the Hon. Secretary of the Photographic Club relating to the adoption of the metric system of weights and measures in photography. This was referred to the Council for discussion, &c.

Dr. W. W. Nichol was elected a member.

Excursions were announced for June 15 (half day), to Berkswell; June 20 (half day), to Warwick; June 10 (whole day), to Shakesperian villages.

Mr. C. T. COX then gave his paper on *Composition*. In the course of his remarks he dealt minutely with the nine laws of composition, viz., Principality, Repetition, Curvature, Radiation, Contrasts, Interchange, Continuity, Consistency, and Harmony, explaining and illustrating each law with large drawings, showing how the amateur photographer should remember and try to utilise these laws when taking landscapes; and afterwards detailed the different kinds of clouds, and cautioned the members when using separate sky negatives to be careful in choosing the sky most suitable to the time and weather when the picture was taken, especially in the case where shadows were seen. His illustrations of cloud pictures were effectively shown, and altogether the paper was very instructive and interesting, and was listened to with marked attention.

The CHAIRMAN said he regretted that a much larger number of the members were not present, and he was sure those who were absent had missed a great treat; he himself would certainly put into practice, when photographing in the field, &c., many of the useful hints Mr. Cox had given them.

Mr. J. EDMONDS proposed, and Mr. HAROLD BAKER seconded, a vote of thanks to the lecturer.

Mr. COX responded, and offered to write out the nine laws of composition, for the same to be printed for posting up in the Club Rooms.

Mr. S. SERSCHALL volunteered to help Mr. Cox by making a set of drawings to illustrate each law.

LEEDS PHOTOGRAPHIC SOCIETY.

APRIL 10.—Mr. Thomas Dawson (Vice-President) in the chair.

Mr. Frank Waddington was elected a member.

Mr. C. H. BOTHAMLEY, F.I.C., then gave a lecture on *The Chemical Effects of Light*. He said the ancients were well acquainted with the fact that many substances undergo change when exposed to air and light, but they failed to attribute these changes to their true cause, and it is only in comparatively recent times that accurate knowledge respecting the nature and cause of these phenomena has been obtained. The action of a prism shows that a beam of ordinary white light is composed of rays which produce very different colour sensations, and differ also in their refrangibility, or the extent to which they are bent out of their original course by the prism. When a beam of white light is passed through a prism and allowed to fall on a screen, we get what is known as a spectrum, in which, when examined, it is easily seen that the yellow seems brightest to the eye, green and orange less bright, and red, blue, and violet comparatively dark; if a thermometer with a blackened bulb is moved along the spectrum it is found that the heating effect is almost inappreciable in the violet, gradually increases towards the red, attains a maximum in the invisible rays beyond the red, and then rapidly decreases; if a piece of paper coated with silver chloride is exposed to the spectrum, it is found that the maximum effect is exerted by the violet and the invisible rays beyond the violet, whilst no appreciable effect is produced by the yellow, orange, and red. It is evident that the maximum effect on the eye, the blackened thermometer, and the silver chloride respectively, is produced in very different parts of the spectrum, and hence it was at first supposed that the luminous, heating, and chemical effects produced by a beam of light are due to entirely different kinds of rays, which were spoken of as light rays, heat rays, and actinic rays. It is now known that this supposition is erroneous. Any ray in the spectrum produces a heating effect when it falls upon lampblack or any similar substance, and chemical effects are not due solely by violet and ultra-violet rays, but may be produced by any rays if they fall upon suitable substances. The decomposition of carbonic acid in the leaves of plants takes place mainly under the influence of orange-red rays; the bleaching of cyanine is effected chiefly by orange rays; a gelatino-bromide plate prepared with ammoniacal erythrosine is more strongly affected by the greenish-yellow rays than by any other part of the spectrum, and many other examples might be mentioned. The effect which any given ray produces depends not so much on the ray as upon the nature of the substance on which the ray impinges, and one and the same ray may produce luminous, heating, and chemical effects. It is a well-established and fundamental principle that a substance can only be affected by those rays which it absorbs. For example, a mixture of gelatine and potassium bichromate is acted upon by the rays which the bichromate absorbs, and is therefore not affected by light which has previously passed through a solution of the bichromate; for the same reason a mixture of ferric chloride and alcohol is not affected by rays which have previously passed through a solution of ferric chloride. Several other instances were given.

Correspondence.

Correspondents should never write on both sides of the paper.

A NEW SHUTTER.

To the Editor.

SIR,—IN THE BRITISH JOURNAL OF PHOTOGRAPHY published on April 26 last, No. 1512, a desire was expressed by you in the "Correspondence" column to know something about a shutter which, with one exposure, would give a prolonged one to the foreground and an instantaneous or shortened one to the sky, as circumstances or the will of the operator might incline, and which, though seeming to be two, was only "one exposure" divided into two parts.

It had been a want long felt by the writer, in his extensive practice of landscape photography, how to overcome the above difficulty, and numerous dodges were tried, notably one by the late Mr. Walter Woodbury, by means of which an irregular-toothed disc of metal was fitted into the hood of the lens during one part of the exposure, and then suddenly withdrawn by a red-coloured handkerchief, and the flap shutter closed at the same time to complete the sky, thus giving a lengthened exposure to the one and a momentary one to the other, the toothed disc preventing any lines forming across the picture. But this at times was found to be very awkward, and it occurred to the writer that if, in conjunction with a pneumatic flap shutter, the same point could be arrived at, it would be as well. And here let me offer a few remarks on the "flap" over the drop, and blind-roller, and diaphragm-slot shutters of the present day. To take a photograph—we must not call them "pictures" (except the yachting scenes which are specially arranged for)—in the shortest possible period of time, seems amongst some gentlemen the height of their ambition. Of course, we all have a right to our own opinion in photography as well as in other matters, but those of us who are the old wet collodion workers, and who aim at making "pictures"—those representations of nature which embody thought and feeling, which speak to others, conveying to their minds happy memories of pleasant days passed, perchance, with loved companions—we (and there are a good body of us to the fore yet, thank God!) like to move upon the old lines, only making use of such appliances of modern times as will enable us to give force to our conceptions. Hence the desire for slow plates and flap shutters, which, by cutting off the top light, which is of no use, and which really, in a great measure, weakens the direct rays from the object, enables one by a moderate exposure of three or four seconds to secure that which is really perfection. Now to make this harmonious as to foreground and sky—to, in fact, equalise the exposure to both—the writer, in conjunction with his friend, Mr. Husbands, optician, Bristol, conceived the present idea, and after many trials worked it out both for single pictures and also for those of the stereoscope, calling the same the "Warner-Husbands Shutter." It embodies the shutters of Messrs. Guerry & Co., of Paris, and of Messrs. Reynolds & Bransom, of Leeds, leaving out certain weighty appendages, and affixing in their place a regulating wheel, giving the angle of the foreground to be exposed, with a positive certainty for such exposure, and the means of releasing the drop at any pace, securing either instantaneously or the exposure of one-sixtieth of a second, or a longer of one, two, or more seconds, entirely at the will of the operator.

It is light, there is no vibration or shake of any kind, and it may be used in any position, slanting to cut off light from windows in interior work, or upright for ordinary views. It has not been as yet brought prominently before the public in advertising its merits, as the inventors believe that, like as "good wine needs no bush," sooner or later its merits will be known, and that it will then lead to a better development, and a healthier state of all kinds of photography, especially of the portable and panoramic stereoscope and slides, for which the same gentlemen are the inventors and agents.

Photographs are enclosed of the two shutters, both of which are in daily and constant use by the writer of this explanation. No. 1 represents the large shutter (which by means of adapters fits eighteen lenses) as being half exposed for a foreground, the drop shutter being ready to fall, on the flap being raised gently or forcibly by the pneumatic bulb, ensuring rapid and slow exposure for the sky. No. 2 represents two shutters (which adapt themselves to six pairs of lenses of various foci) which move simultaneously, and by which even more rapid exposures can be obtained than by the larger size. There is a regulating pin in the smaller sizes, by which perfect unity of action is secured.

Messrs. Henry Husbands & Sons, opticians, Bristol, who are the agents for this shutter, &c., will answer every inquiry as to price.—I am, yours, &c.,

HARRING WARNER.

[Our esteemed and veteran correspondent has informed us very clearly what this shutter can do, but has not given such details as to its mechanical operation as we know our readers would like. Nor do we quite glean this from either the drawings or photographs received. So far as we can perceive, it consists of a flap raised, either quickly or slowly, by means of a pneumatic ball, which flap, when raised to the top, releases a drop shutter, which suddenly cuts off the exposure by dropping in front of the lens. But this was what we claimed when describing the shutter of Messrs. Reynolds & Bransom,

of Leeds, and we have failed to discover, from the description or drawings of Mr. Warner, wherein the one differs from the other.—Ed.]

CUSTOM HOUSE REGULATIONS.

To the Editor.

SIR,—Some time since there was a correspondence in your JOURNAL respecting the difficulty several amateurs had met with in attempting to pass their exposed plates through the Customs without some over-zealous official opening them. We thought it would be interesting to your readers to know that the matter had been brought up in the House of Lords by Lord Ribblesdale and replied to by the Marquis of Salisbury. The reply is in itself so exceedingly satisfactory that it will doubtless relieve the minds of all amateurs who are travelling abroad, or who intend to do so. We append an extract from one of the "dailies," which will, we think, interest all concerned.—We are, yours, &c.,

Pro The London Stereoscopic and Photographic Company,

BUTLER HUMPHREYS, Manager Amateur Department.

The following is the extract alluded to:—

Lord RIBBLESDALE, in calling attention to the Custom House regulations with regard to undeveloped photographic plates, justified his action by relating an incident which occurred at Plymouth lately on the arrival of a steamer with passengers from abroad. Among the passengers was a friend of his who had a fondness for photography, and among the friend's baggage was a box containing a number of undeveloped sensitive photographic plates. Explanations were useless; the Custom House officer refused to pass the box, on the plea that the plates might contain something of an indecent or immoral character. As no dark room was to be found the friend had to stay the night at Plymouth, and on the plates being developed the following day the most indecent or immoral thing discovered was a picture of a picnic party on the crater of a volcano. He supposed that all this bother was rendered possible by the regulations. The regulations certainly had a paternal smack about them which he did not much care for, and he should like to hear what explanation the Government had to offer on the subject.

The Marquis of SALISBURY supposed it was his duty to defend the Government, and he could only defend them by saying that this particular Custom House officer appeared to have acted with inconceivable stupidity. Formerly there was a pursuit of dynamite, but now it seemed there was a pursuit of decency. The pursuit of decency was highly praiseworthy, but it should be pursued with some discretion. Elaborate arrangements were not necessary to avoid such a misadventure in the future. A regulation had been issued at the Custom House, that if sensitive plates required to be examined, they should be examined in a dark room by the light of a red lamp. In that way he hoped all possible objection would be removed. He was only sorry the knowledge of science had spread so little in certain branches of Her Majesty's service that it should be necessary to issue such a regulation.

PHOTOGRAPHING IN NORWAY.

To the Editor.

SIR,—Your correspondent, Mr. F. Coop, will find the exposure in Norway to be about one and a half times that of England; usually it is considerably more, because of the prevailing black and dark-brown tone of the rocks. I have photographed along the entire coast, from Christiania to the North Cape, and shall be pleased to answer any questions that Mr. Coop may put to me, either through this JOURNAL or privately. If he takes Carbutt films, Paget "50 times," or Ilford red label, he will be able to take instantaneous views all along the coast, and fairly well exposed with f-11 and Kershaw shutter between 10 a.m. and 3 p.m. in June, July, and August, but the rocks will not develop out all detail with f-16, except under very favourable conditions, sun lighting them up, or forming distant background to seascape.

The neighbourhood of Christiania, Hønefoss, and along the coast, Christiansand and neighbourhood, Stavanger, and the lovely drive from Stavanger to Odde, will well repay a series of plates. So will the Geiranger and Nord Fjorda. The best scenery is all above Bodø and Toomsø, but the Loloden group is very grand and interesting. Baedeker's *Norway and Sweden* contains all the maps he can possibly want. I forgot to mention the Salten Fjord, which to my mind is much the grandest fjord in Norway. One disembarks at Bodø, and takes the little bi-weekly steamer that runs up and back every three days. If Mr. Coop stops at Bodø will he let me know, and I will give him a note of introduction which will be of some service to him there.—I am, yours, &c.,

G. LINDSAY JOHNSON.

11, Stratford-place, Regent-street, W., May 21, 1889.

A CORRECTION.

To the Editor.

SIR,—Will you kindly allow me to make a correction to your published report in last week's BRITISH JOURNAL OF PHOTOGRAPHY of the meeting of the University College Photographic Society on May 18th?

It is stated therein that I exhibited some examples of Pretsch's photogalvanographic process. I certainly showed one, the well-known print of Don Quixote in his study, but the numerous other specimens which were displayed by me were of Obernetter's simple photogravure. As these proofs excited more interest and admiration than anything that had gone

before on the occasion, it is only just to the representative who kindly furnished me with the series for exhibition that this should be mentioned.

While Pretsch's process is in question, how is it that this marvellously excellent system of reproduction is now so entirely neglected, if not quite unknown, to our present generation of photo process workers?—I am, yours, &c.,

28, L.inster-square, W., May 25, 1889.

HENRY E. DAVIS.

PRESERVATION OF SOLUTIONS OF PYROGALLOL.

To the EDITOR.

SIR,—The thanks of the fraternity are due to Mr. Burton for his elaborate paper on the solutions of pyrogallol which appeared on the 17th ult. Few of us have the time, means, and thought to carry out such a series of experiments, which appear to me to be the right way to arrive at the proper value the different substances possess. I should have liked to have seen sodium sulphite, as well as the sulphate, noted, also meta-bisulphite of potassium as well as the bisulphate. Can he give in a future number the effect of these upon the keeping of the pyrogallol?—I am, yours, &c.,

W. G.

Exchange Column.

*. No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

Newton's 7½×5 camera, six double slides, for whole-plate, three slides, or head-rest and cameo press.—Address, R. SIMMONS, Galway.

Ross' No. 2 C.D.V. lens in exchange for whole-plate or half-plate rectilinear or symmetrical.—Address, W. SAUNDERS, Dickleburgh, Norfolk.

I will exchange a Gem camera having nine lenses for a Rudge's or Rover Safety bicycle.—Address, J. POVEY, Photographer, 124, Wilbraham-street, Ribbleson-lane, Presloo, Lancashire.

Wanted, pair of good stereoscopic lenses, also detective lens by good English maker; exchange in musical instruments or lantern slides.—Address, W. A. BEZANT, 12, Victoria-terrace, Leamington Spa.

Hare's half-plate camera, new couch, and two Scholzig's graduated backgrounds (7×5), for exchange. Wanted, Seavey's interior and exterior backgrounds.—Address, W. COLES, 60, Queen's-road, Watford.

Will exchange Marion's print washer, cabinet barnisher, and Newbold's view finder, for half-plate Universal studio camera and slide or a 12×10 leather case for camera and accessories.—Address, A. WHETTON, Market-place, Deddington.

Cabinet lens by Vogel, Philadelphia, diameter three inches, focus nine inches; also Marion's C.D.V. embossing machine, new. Will exchange for posing chair with more than one back, backgrounds (exterior and interior), or studio curtain.—Address, HORTON, Photographer, Caroline-street, Cardiff.

Answers to Correspondents.

*. Communications relating to Advertisements and general business affairs must be addressed to "H. GREENWOOD & Co.," 2, York-street, Covent Garden, London, W.C.

All matters for the text portion of this JOURNAL, including queries for "Answers" and "Exchanges," must be addressed to "THE EDITOR," 2, York-street, Covent Garden, London, W.C. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.

PHOTOGRAPHS REGISTERED:—

A. G. Petherick, Taunton.—Two photographs of H.R.H. the Duke of Cambridge on the review ground, Taunton.

A. Hamilton, Bristol.—Three photographs of the lion "Hannibal."

T. Bromwich, Bridgnorth.—Photograph of Palmer's Hospital.

S. J., LEONARD, and "TWO-YEAR-OLD."—See leading article in present issue.

MORS CONSILII.—The negatives are very bad, and the retoucher ought not to have wasted work upon them.

ALFRED.—Celluloid is practically a compound of a nitro-cellulose with camphor. Xylonite is a similar compound.

LOWESTOFT.—We have never compared the lenses against each other. All those on your list are good, and work with about the same aperture.

EAST ANGLIAN.—1. Fix the plates in hyposulphite of soda and then precipitate the silver with sulphide of potassium.—2. Consult formulae in later ALMANACS.

FERROTYPE.—So far as we are aware, such plates are not an article of commerce at the present time. They were once in the market, but we believe there was very little demand for them.

X. X.—Permission to take photographs in Kew Gardens may be obtained from Mr. Thistleton Dyer, at the Gardens. Write to him. You will not be admitted with your camera without a permit.

G. R.—By artificial ivory do you mean what is known as ivoryine? If so, that may be procured from most fancy stationers. Carbon prints transferred to it are very effective. We have frequently recommended its use in this direction.

S. NOKES.—Zinc dishes will not do for the hyposulphite of soda solution. You had better obtain an earthenware dish for the fixing bath. If large enough, common brown baking dishes will answer every purpose, and they are very cheap.

DOMINO.—As you ask for free criticism, we say that the lighting and posing are of good average quality. With regard to the retouching, we cannot say very much in its favour. Much of the modelling and drawing are lost in many of the faces.

REV. J. CARTER BROWNE, D.D., desires to thank the very numerous correspondents who so kindly sent him the meaning of the letters "O. H. P. C." What goodwill exists among photographic brethren, and what a useful medium is THE BRITISH JOURNAL OF PHOTOGRAPHY!

S. S.—If you use the Royal arms and style yourself photographer to the Queen you render yourself liable to a heavy penalty unless you hold the Royal warrant. The mere fact that you have taken a portrait of Her Majesty does not confer the right to use the Royal arms and title of photographer to the Queen.

J. W. COPLE.—Try the effects of slightly damping the paper before printing. You can scarcely expect to get a very perfect result at the first attempt with any new process, so don't be discouraged by a failure or two. Much depends upon the hygroscopic condition of the paper in the direct platinum printing process.

WM. MCK.—The sudden frilling of the plates with which, for months past, you have been working so satisfactorily may well be accounted for by the sudden and abnormal rise in the temperature we had last week. By this time, with the cooler weather, no doubt your trouble has disappeared. If not, immerse the plates in a solution of alum prior to putting them into the fixing bath.

SANDY GRANT.—So far as we are aware, "silhouette machines" are not articles of commerce, and we cannot say where you will find an illustration and full description of one. You might possibly find one at some country fair, but we imagine they are things of the past. All that is really necessary for the purpose is a rod pivoted, gymbal fashion, so that it can move freely in every direction, very much the same as shown in your sketch.

W. ANNOT.—1. There is always a certain amount of risk in purchasing second-hand apparatus without a trial, except from respectable dealers. The price named seems very low, but as no makers' names are mentioned, we cannot give any idea of its value.—2. For general purposes a lens of the rapid type is far preferable to one of the wide-angle series.—3. With a "rapid" you will experience no difficulty in obtaining instantaneous pictures at the seaside on a fine day.

Z.—As you cannot get a north light, and must have either east or west, which will be the best will depend very much upon what time in the day it will be most used. If the greater part of the work be done in the morning, then the west side had better be glazed. If in the afternoon, the east side. We should advise you to have a ridge roof, and perhaps it would be more convenient, if you want the studio for professional work, to glaze both sides and have tolerably dark blinds to stop out the sun as required. The proportions you suggest are very good, but, for full-length portraits, a little larger would be better, as that would enable you to work with lines of sufficient length of focus to obtain the best results.

RUSSELL STREET writes: "I am thinking of working the wet collodion process again; would you kindly advise me as to what sized nitrate of silver bath I should get for 8½×6½ plates so as to allow for the moving the plate up and down and from side to side during the process of sensitising the plate, and also what kind of dipper is the best?"—In working the wet collodion process it is always convenient to have the vessel containing the silver bath somewhat larger than is necessary to take the plate. For a whole-plate we advise what is termed a 10×8 bath to be used. Glass is as good as anything for a dipper. Ebonite is also good, and is not so liable to get broken. For ourselves we prefer dippers made of pure silver wire. These are somewhat costly, but they will last for ever.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, June 5, 1889, will be *Films*. Saturday outing at Pinner. Bank Holiday outing at Aylesford, Kent. Trains from London-bridge, Cannon-street, and Charing-cross.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1518. VOL. XXXVI.—JUNE 7, 1889.

RECOVERING BROMIDE FROM WASTE PLATES AND EMULSIONS.

At a meeting of one of our metropolitan photographic societies on Tuesday evening, a question was informally put, as to the best means of utilising or recovering the silver from a quantity of gelatine emulsion that had gone bad. The answer we gave was to spread it upon plates of glass, coat thickly with it the bottom and sides of a large flat dish, or adopt any similar means by which it could be brought into a somewhat pellicular form, and then submit it to the action of a solution of hyposulphite of soda, which might be renewed, if necessary, until the whole of the bromide was found to be dissolved.

Treatment of this nature applies equally to plates that have been found untrustworthy as to emulsion that from any cause has become deteriorated. Of these we have seen many dozens treated in the way indicated. They were stacked in a light basket, having been first separated from one another to a slight extent by a length of string interposed zigzag between them to ensure the liquid having free access to the surfaces, and were then lowered down into a vessel of solution of hyposulphite of soda. While in this the basket was moved up and down at occasional intervals to promote a free circulation of the solvent liquid, and when the whole of the bromide had been dissolved, and a spray of water directed against the plates to effect the removal and utilisation of such solution as adhered to them, the basket and its contents were in like manner transferred to a vessel of plain warm water, to effect the dissolution of the gelatine from the surfaces of the plates.

But it is with the hyposulphite of soda solution, now richly charged with silver, that we have to do at present. The story of its utilisation has been often told, and is well known to every veteran, but for the benefit of those whose experience is as yet limited we tell it again. If into a solution, such as that now on hand, a solution of potassium sulphide (the liver of sulphur, or sulphuret of potash of the druggist) in water be gently poured, accompanied by stirring, a dense black precipitate will immediately take place. The addition should be continued until, upon taking up a little of the waste solution into a test tube and adding one or two drops of the sulphide, it is seen that no further precipitation takes place. Avoid adding any more to the hypo solution than barely suffices to precipitate the silver.

The black substance thrown down as mud is silver sulphide, and it must be washed by several changes of water, each in turn being drawn off by decanting. With due care not one particle of this precious precipitate need escape. Preserve it carefully, for it can all be converted into nitrate of silver or into metallic silver, the former being the most easy for the

amateur, whose chemical appliances may not comprise a crucible or modes of melting metal.

Place the still moist sulphide into a glass or porcelain vessel, and pour into it, by very little at a time, nitric acid, allowing plenty of time for it to act after each addition. In due course it will be all dissolved, and it is now a solution of nitrate of silver, and must be poured out into an evaporating dish to crystallise.

But it will still be rather crude and somewhat acid; hence it should again be dissolved, this time in distilled water, and be once more crystallised, after which it may be utilised as the whim or requirement of the owner suggests. All the vessels employed should be washed with distilled water, so as to allow none to escape as waste.

The foregoing method presupposes the emulsion to have been spread on glass or otherwise. But it is also possible to obtain all the silver bromide, as bromide, from emulsion the gelatine of which has deteriorated. Ehrenmann's method is one which can be recommended for this purpose. The emulsion, after being diluted with sufficient quantity of water, is heated to about 150° Fahr., and to each gallon of mixture is added six ounces of nitro-sulphuric acid. Let the heat be continued for an hour, during which time the mixture is occasionally stirred up. When cool and settled it will be found that the acid has destroyed the viscosity of the gelatine, and that the bromide has settled at the bottom of the vessel.

The acid liquor is poured off and may be used again for a similar purpose. The bromide is repeatedly washed, and is ready for being again emulsified with fresh gelatine.

PRETSCH'S PHOTO-GALVANOGRAPHIC PROCESS.

In a letter in our correspondence columns last week, about the above process, Mr. Davis asks "How it is that this excellent system of reproduction is now so entirely neglected, if not quite unknown, to our present generation of photo-process workers?" Probably it is only our older readers who are familiar with this process; still, most of the younger ones have, however, heard of it, and the excellent results which were produced by its agency. It may, therefore, be desirable to enlighten the latter as to what the process really is, the principle upon which it is based, and to explain why, as our correspondent says, it is now so entirely neglected.

In an intaglio printing plate, it is scarcely necessary to explain, those parts which are to form the darker portions of the picture are depressed, while the others are not. In point of fact, an intaglio plate is precisely the reverse of a surface

or typographic block. In the latter, it is the raised portions that carry the ink, while, in the former, it is the depressed parts that contain the ink. This being the case, it might well be surmised by the uninitiated that intaglio plates were very easy to produce, inasmuch as it would only be necessary to make an electrotype *replica* of a gelatine relief to obtain what is required. This is correct up to a certain point, and there only. For, in practice, another condition is essential, namely, that the sunken parts must possess a certain degree of roughness, or grain, which will retain the ink when it is applied; otherwise it would be wiped out in the operation of inking in the plate. Furthermore, this grain must be deeper and more decided in the blacks than in the half tones. Obtaining a grain of a suitable character is one of the principal difficulties in the production of intaglio printing plates.

Briefly described, this is how the Pretsch process is, or rather was, worked, for we shall write in the past tense, inasmuch as the process is not now employed. A glass plate was coated with gelatine, containing bichromate of potash, a salt of silver, and sometimes other substances. When dry, the plate was exposed to light under a transparency. After printing, it was immersed in cold water. The action here was not only to dissolve out the unaltered chromium salt, but to cause those parts which had been protected from light to swell up, and that, too, in proportion to the protection which had been afforded by the transparency. But this was not all, for the raised portions were rough and reticulated, and, what is more, the reticulation was coarser or finer in proportion as the different portions had been protected, or otherwise, from the action of the light. The high lights of the picture, which had received the full force of the light, did not swell at all, and, consequently, had no grain—being perfectly smooth—that is, supposing the exposure was correctly timed.

It will now be seen that the plate, thus produced, was exactly the reverse of what is required in a printing plate. That is to say, what should be the darker portions were in relief, while what should be the lighter ones were, more or less, in intaglio, the former being granulated, while the latter were not. All that remained now was to take an electrotype cast from this relief to obtain the printing plate. But this had to be done while the gelatine film was still wet and swollen, in order to retain the necessary relief to produce sufficient depth and ink-holding grain in the finished plate.

All who have attempted to deposit copper on a wet gelatine film know quite well that it is not an easy thing to accomplish. The acid sulphate of copper solution has a strongly solvent action on the gelatine itself; consequently, unless the whole surface be covered very quickly with a rigid coating of metal, the crispness of the grain, so essential for holding the ink, would be lost. And it so happens that when the gelatine is most in relief and has most grain, it is then in a more soluble condition than when it has been hardened by the light's action, and, as a matter of course, is first to be acted upon by the copper solution. Hence the grain, which it was so necessary to retain, was the first to be attacked. The consequence was that many of the plates, when a sufficient deposit of copper had been obtained, were found to be nearly devoid of ink-holding properties in the shadows, and were, therefore, useless unless a considerable amount of hand work by skilled engravers was expended upon them. This, it goes without saying, rendered the plates very costly by the time they were finished.

Yet, more than thirty years ago, plates were made by the Pretsch method, some of which did not require an excessive

amount of hand work to make them good, as many of the specimens, still in existence, will show. However, the Pretsch process did not prove a commercial success in this country. Neither, at that time, did any other photo-engraving process, for that matter. The Fox-Talbot process, which was contemporary with Pretsch's, was not worked commercially, yet it was capable of yielding most excellent results. Possibly this was, in a measure, due to want of enterprise on the part of the inventors, coupled with the fact that the period was not then ripe for photo-mechanical processes. The processes were before the times.

Now as to the query of our correspondent, "Why is the galvanographic process of Pretsch so neglected?" The reply is simple. The process has been superseded by other methods by which the same end may be attained by easier and more satisfactory means.

All those who work any of the photo-engraving processes, commercially, keep the details of the methods they employ as profound trade secrets. But it is no secret that some, at least, of them are based upon the Pretsch and the Talbot principle.

A NOTE upon photographing colours in shades duly proportionate to their effect upon the eye was recently read before the Paris Academy of Sciences by M. G. Lippmann, in which the manner of use of coloured glasses was well worked out. The author commenced his remarks by pointing out the well-known difficulties presented by ordinary plates when colours were to be photographed. He gave forty, for example, as the number of times the exposure for green required over that for blue, and he went on to say that, although the orthochromatic plates of "Vogel, Obernetter, and Attout Tailfer" were far better for the purpose, they were a long way from being perfect. M. Lippmann's system is to make what he terms a "rational and systematic use of the plates," and, by so doing, obtain absolutely just values in the negative. His *modus operandi* is first to place in front of the lens a piece of blue glass and expose long enough for the blue rays only to impress themselves. Next, without touching the apparatus in any other way, and taking care not to shake or disturb the camera, the blue glass is replaced by a green, and the exposure is continued long enough for the green rays to become impressed. It is explained that the green glass has been chosen with great care, so as to select a sample that did not permit the least trace of blue to pass through, so as to have no fear of over exposing, owing to the presence of the quick-acting blue rays. Finally, the red rays have their turn: a piece of glass again well chosen, this time so as to keep out both blue and green rays, is placed before the lens in lieu of the green, and the plate exposed for the right length of time. The final result is stated to be a perfect photograph, *i.e.*, a negative quite clear, without brown patches, and in which green leaves and yellow and red draperies are represented as finely modelled, as in a well-executed engraving. We can only say that M. Lippmann has been fortunate in finding such perfect monochromatic pieces of glass.

An announcement is made from America that Professor Charles S. Hastings, of New Haven, Connecticut, has been so able to utilise the Jena glass as to produce objectives without secondary aberration. He has made a small telescope of two and three-quarter inch clear aperture, which gave images of most "astonishing beauty," in which the familiar purple was absent, or only visible upon the closest scrutiny, even when magnifying powers greater than forty to the inch aperture were used. He states that "by reference to the records I have made with many telescopes the power of the new telescope was estimated as equivalent to a three and a half-inch objective of the ordinary construction. The meangain, after a number of experiments, was about twenty-three per cent. over the best instruments yet constructed on the old lines," this being a rate of improvement that is, as the in-

ventor says, higher than would be generally admitted as possible by most opticians.

A new substance, which will attach to itself great interest from a photographic point of view, quite apart from its purely chemical interest, has lately been described by M. Péchard. It is a mixed acid derived from oxalic and molybdic acids, and hence is termed oxalomolybdic acid. It crystallises in regular forms, and is quickest and best made, perhaps, by dissolving the viscous mass formed on evaporating the saturated solution of the acid in dilute nitric acid, evaporating it in a dessicator. Now these crystals when dry are permanent either in the sun or when protected from light; but the moment they are allowed to become moist they begin to take a blue colouration in the light. Writing may be made with the solution in a weak light, and it will be quite invisible, but the moment the sheet of paper is placed in the sun's rays, the writing starts out in blue characters. In solution, however, the liquid is quite colourless.

It is stated that if a sheet of paper be sensitised with a saturated solution of this new chemical, the sheet may be placed under a negative, and a good picture in blue printed out. The image so produced, however, is destroyed when the sheet is moistened, but may be retained by exposing to a gentle heat for a few minutes, when the blue is turned to a grey which is permanent. It would seem as though something practical might be worked out from this newly invented substance.

We have on previous occasions pointed out how erroneous is the popular view that glass is a perfectly stable substance that is not acted upon, at any rate, by water; and in a foreign chemical journal this is emphasised by a description of a process for testing glass according to the colour reactions obtainable from the substance dissolved out by water. It is evident that such qualities as this may have a decided bearing upon the action of a gelatino-bromide film upon glass. An idea of the action of water on glass may be formed by sealing up a solution of iodine for a few weeks in a glass tube, the liquid becomes quite decolourised, and the colour can be brought back by adding dilute sulphuric. Again, when a trace of a very dilute solution of silver acetate or nitrate is added to an aqueous solution of starch and pure iodine, the blue colour is destroyed, owing to the combination of the free hydriodic acid; but if a little powdered glass is added, an alkaline iodide is formed with its aid and the blue colour is restored.

THE article goes into details useless to our readers, but in its concluding paragraphs we find some facts recorded, which, besides their practical bearing, throw light upon the causes of the retention of a photographic image upon a negative from which the film has been cleaned off. Herr F. Mylins states that the very worst sample of glass can be made capable of permanently resisting the action of water by a very simple plan. It is first left in cold water for several days, and then heated to a temperature of three to four hundred degrees centigrade. When so treated the tests for the extent of solution already described fail to give any result, the glass is insoluble. From these facts it would appear quite certain that an old negative would be more remarkable for not leaving an impression on the glass than for producing one, as the action of water would clearly be varied by the extent to which it could gain access to the surface of the glass below it, and this would be governed by the presence of a greater or less amount of matter in the film, this "matter" being in effect the image.

THE *Illustrated London News* has, in its last number, quite a number of views of scenes on a yachting regatta, which took place the previous week; many of these white wings having been successfully shot at and captured by Mr. Rouch, who was on board the press-boat, with his Eureka Detective Camera. No draughtsman could possibly have managed to secure such accurate transcripts of the details of this regatta as did Mr. Rouch with his neat little detective. The same journal, the week preceding, also contained several illustrations of

the animals in motion obtained by Mr. E. Muybridge, and which have been employed by him in elucidation of his lectures delivered at the Royal Academy, the Royal Institution, and other societies.

THE WHOLE ART OF PHOTOGRAPHY IN A SERIES OF EASY PROGRESSIVE LESSONS.

CHAPTER IV.—THE FERROUS OXALATE DEVELOPER.

COULD it be proved that one developer is in every respect better than another, then would there be no necessity for writing about or even tolerating any other than that one. But opinions are divided, a fair proportion of the public preferring to adhere to iron rather than to pyro or hydroquinone, and there is no doubt that numerous very fine negatives are produced by its agency.

The ferrous oxalate—so called on account of its consisting of iron and potassic oxalate—is a developer which is simply made, requiring neither scales nor weights in its preparation, works always well, costs very little, and does not stain the hands like pyrogallol. It is most easily made in the following manner:—

Having procured two large bottles of clear glass—common spirit bottles will serve if there is nothing better procurable—fill them nearly full of water, and into one place a quantity of neutral oxalate of potash (potassic oxalate), and into the other some protosulphate of iron (ferrous sulphate). As what we desire is a saturated solution of each, it is necessary that so much be added as to render the water incapable of dissolving it all, even after being well shaken up and allowed to stand for this purpose. There will thus be, or ought to be, a quantity of the crystals remaining undissolved in the bottom of each bottle. This must not be considered as lost, because when in course of time it becomes necessary to fill up either bottle with water to keep up the stock supply in lieu of what will have become extracted for use, the crystals dissolve and keep the solution up to the proper strength. Have these bottles labelled respectively "ferrous sulphate" and "potassic oxalate," and we are now ready to begin work.

The plate, having been exposed and brought into the dark room, is placed face up in a tray. The developer must have been previously mixed, and is composed of three parts by measure of the oxalate solution, and one part, also by measure, of the iron solution. The iron is poured into the oxalate, and immediately strikes a deep red colour. Suppose that two fluid ounces of developer will be considered requisite for covering well the plate about to be developed, then, according to the above, it will be composed of half an ounce of the iron, and one and a half ounce of the oxalate solution. Or, if cubic centimetres be the standard of measurement, a proportionate quantity would be fifteen of the one solution to forty-five of the other, which would give sixty c.c. of developer—not greatly in excess of two ounces.

When this developer is poured over the plate the image appears with considerable rapidity, and after it has acquired the requisite intensity, ascertained by raising it up and looking through it against the coloured light in the dark room, it is rinsed with water and transferred to the fixing bath.

But with some makes of plates the developer may not take so kindly to the surface of the plate but what minute air-bubbles may adhere, which will form white or transparent spots in the negative. There are two means by which this may be prevented: one is to thoroughly wet the surface of the plate with plain water previous to applying the developer, another being to ensure the contact of the developer with the surface by sweeping a hard tuft of cotton wool firmly across the surface immediately after the developer is applied. In either case no spots will possibly result. Some operators prefer to employ the ball of the finger for this purpose.

It may be that, especially during warm weather, the proportions we have given are so strong as to bring out all the details much quicker than is desired. When this is the case reduce the activity of the developer by increasing the proportion of the oxalate solution. This may be done, and frequently with very decided advantage, by even making the proportions as one part of iron to six or eight of oxalate.

We have hitherto assumed the potassic oxalate and the ferrous

sulphate to have been purchased of a quality properly adapted for the special work in hand. But we have known instances in which even fine samples of these salts did not give results so satisfactory as were desired. A few (very few) crystals of oxalic acid dissolved in the potassic oxalate solution will scarcely ever fail to render and keep it in good working order, while we, in our own practice, invariably add a few drops, per pint, of sulphuric acid to the protosulphate of iron solution. This ensures its remaining in a healthy condition and not suffering from per-oxidation.

But is there any reader so far removed from a photographic store as to be unable to obtain neutral potassic oxalate? Then, fortunately, he may be enabled to make it cheaply and plentifully for himself. No country village so ill-provided with the requirements of life but where there is to be obtained oxalic acid and carbonate of potash, known frequently as pearl ash, employed in the domestic wash-house.

Into a tall jar pour a quantity of water that will only partly fill it. Suppose this quantity to be a gallon, throw into it a pound of the carbonate of potash (which, by the way, is sometimes sold as salts of tartar), and stir with a wooden spatula until it is dissolved. Then throw in oxalic acid slowly, which, as it dissolves, will give rise to a brisk effervescence. When this effervescence ceases, by the alkali having been neutralised, it will be found that the weight of acid used has been considerably less than the potash salt. The resulting liquid is a saturated solution of neutral oxalate of potash, and when decanted off and filtered, forms a stock solution for the developer. It will not be found to differ in its action from the purest crystals dissolved in distilled water, a fact we have just verified by comparative trials made during the course of writing this article.

And here we may observe that this "home-made" neutral oxalate solution has just been found to have acted its part admirably in developing some bromide prints on paper, when mixed, of course, with the iron salt as described, and used much weaker than in the proportions recommended for negatives.

THE EMULSION PROCESSES OF PHOTOGRAPHY.

[A Communication to the Bath Photographic Society.]

THE abundance of material which has so far engrossed our attention must, I imagine, be singularly gratifying to the promoters and well-wishers of this energetic Society, as well as proving highly instructive to all of us who have been fortunate enough to attend the meetings. This state of things can only be achieved where selfish motives do not govern, and the mutual desire to help each other, as expressed in the first paragraph of our prospectus, "The general interchange of views and ideas as to the progress of the art," is honestly carried out. It would be absurd for any one to state that this condition is not generally observed, and I trust that as years roll on the solid advice given by that well-known representative of science, James Glaisher, F.R.S., when he presided over the deliberations of the founders in September last, will be kept steadfastly in view. To-night it is pleasant to note we have already got through more work than would suffice as an average at some other society meetings, and I am afraid that the time I am occupying would be more advantageously spent on another topic less comprehensive than the emulsion process of photography. And here let me state that, in introducing the subject placed on the notice paper, it was the intention to review some of the capabilities of emulsions for the information of inexperienced members of this Society rather than to deal with any one process in all its details. A general idea gathered, detailed papers relating to a specific subject may then be of increased interest, and we are fortunate enough to have experts amongst us who will doubtless lend their assistance when requested so to do.

What is an emulsion? An emulsion has been defined as oil divided and held in suspension in water by means of mucilage or some other colloid body, but we photographers use the term to signify the complete suspension of any powder which is insoluble in the vehicle chosen; the latter must, however, possess the quality of drying at moderate temperatures. The proposal to employ such an emulsion, as we understand it, composed of certain metallic sensitive salts supported in a convenient vehicle, is probably within the recollection of some present, although I think it dates back fully thirty-five years. According to Dr. Eder, in *Modern Dry Plates*, published in 1881, Gaudin, as far back as 1853, wrote the first papers on the subject of a collodion emulsion, in which he alluded to analogous experiments he had then made with albumen and gelatine.

Following up this gentleman's experiments, we find a few years later, 1861, he published a collodion emulsion process, in which silver iodide and silver chloride are described, and to which he gave the name of photogen. He also suggested the spreading of a chloride of silver collodion emulsion on paper, as a substitute for printing on albumen paper, but it does not appear that he achieved any marked advantages over the processes then in general use, even if the results were of equal utility. It, however, serves to indicate the starting point from which many later modifications and improvements originated. The practical advance may be said to have commenced four years later, when the collodio-chloride process of Simpson, and the collodio-bromide of Sayce and Bolton, were published. The first-named was designed for printing positives right out upon paper or glass, and the second was intended for the production of negatives. In neither case was the silver halogen employed in a pure state; organic compounds were associated with them. To-day both are in use for the making of positive images on glass, that containing chloride being employed on paper as well. It is a question which of the two important and well-defined processes have, or may eventually, most influence the progress of photography. If we follow either, it leads us up to the methods practised at the present time. The collodio-chloride emulsion process of Simpson as first published was incomplete, but with the improvements of Swan, Bovey, Tunny, and others, a high degree of efficiency was reached, and an adaptation we find in the so-called Aristotype paper, now commercially issued in Germany and America, and imported into this the country where it originated. The present success of this method of printing on a paper coated with a sensitive emulsion, which will retain its properties unimpaired for a considerable time, and then yield excellent results, is rather due to the nature of the paper basis which supports the emulsion, than the particular collodion or sensitising compounds emulsified. I have never been able in this connexion to trace any chemical influence exerted by collodion in combining with silver, as albumen and gelatine undoubtedly does. This is no drawback, as suitably prepared silver compounds darken in daylight with sufficient rapidity for the ordinary purposes of printing out, and yield rich positives, which can afterwards be modified in colour, if desired, by the action of the toning bath.

Differing as regards the vehicle and the method of preparation, we have an analogous process for printing-out positives by means of silver chloride in conjunction with organic substances, combined and emulsified in a practically colourless gelatine, the strength of which may vary between ten and forty grains of the colloid to each ounce of water. Prints of this nature were first made in 1866, and described by Palmer in the *Photographic News* at the time; but no practical use appears to have been made of the information then given. Captain Abney, in his Cantor Lectures, drew especial attention to the possibilities of this process and gave formulae. An extended series of experiments on many organic compounds, combined with silver chloride emulsified in gelatine, and spread on white surfaces, were jointly carried out a year or two ago by R. Offord and myself, and the results embodied in a series of articles specially written by us for the pages of the *Photographic News*; doubtless the conclusions we arrived at, and the manipulatory details given, are familiar to those who have opportunity to study these subjects, and need not be further referred to here. Like the collodio-chloride emulsion, the mixture compounded by an approved formula can be spread thinly upon any non-absorbent surface, such as opal or strong paper previously covered with a substratum. This may consist of arrowroot, or a ten per cent. plain gelatine solution, rendered partially insoluble with chrome alum. An emulsion of barium sulphate in gelatine makes a capital covering for the paper, and is non-absorbent if the correct amount of chrome alum has been added. Aqueous solutions of resins are likewise suitable in cases where a smooth polished surface is a desideratum. Upon any of these substrata the liquefied and sensitive emulsion is spread in an apartment shielded from the influence of daylight, and, as soon as dry, is ready for printing. If, however, matt surface prints are required, then there is no necessity to use any preliminary coating whatever, as the absorption of a liquid emulsion containing thirty or forty grains of gelatine per fluid ounce is not very considerable, even with porous paper.

The preparation of the sensitive emulsion is such an extremely easy matter that no one need hesitate to attempt a few experiments in this direction. I think there is much more to be discovered about this interesting process, for we have by no means exhausted the combinations which are reasonably likely to be beneficial in producing an effective and rapid printing surface. The chief obstacle is a liability for insolubility to occur some time after the emulsion has been prepared. Potassium salts are apt to bring this condition about very quickly, thus spoiling the emulsion entirely. Some other agents act in a similar manner—often before it is possible to coat the intended

surface. As regards rapidity of action, an emulsion can readily be prepared which will have twice the printing speed of sensitised carbon tissue or of platinotype, and consequently five or six times that of layers of ordinary silver chloride in coagulated albumen. Further, the process is absolutely unfettered by any restrictive conditions, which is rather remarkable in these days of patents.

I will now proceed to make an emulsion of the kind referred to, in order to illustrate how simple is the method of preparation. I will use, for convenience, a citrate salt as my organifier, although nearly all the vegetable acids, in some form or other, can be introduced. These mostly present special characteristics—some useful, others to be avoided.

We have here, then, the materials—gelatine, silver nitrate, and an alkaline chloride—and as the kind of organic salt we wish to form is of some importance, we will make ours a citrate for the occasion, with citric acid and ammonia. We must bear in mind that citric acid added to a solution of silver nitrate does not produce silver citrate, but only acidified silver nitrate. It is, however, another matter if we use a citrate salt such as ammonium, magnesium, or sodium citrate, for then the nitric acid in combination with the silver leaves the metal for the alkaline base, and the result is an interchange by which we get a compound of silver and citric acid—silver citrate and the corresponding alkaline nitrate.

We will take 20 grains of citric acid in 100 minims of water, and, to produce ammonium citrate—a deliquescent salt—add sufficient strong ammonia to nearly neutralise the acid, leaving litmus paper still decidedly red, which, for convenience, we call A. In another vessel, B, we take 45 grains of gelatine, dissolved in one ounce of water, and mix with A. We next take 45 grains of gelatine, 6½ grains of ammonium chloride, and dissolve in one ounce of water: solution C. Then 40 grains of silver nitrate dissolved in 180 minims of water to form solution D. C and D are next mixed (not in daylight), then altogether at a temperature very little above melting point.

The emulsion now formed contains a slight excess of silver nitrate, and more nitrate of ammonia than we desire, so in order to get rid of it, we let it set into a stiff jelly, then break it up into shreds by pressing the solid mass through the meshes of coarse canvas, or cut it up into small pellets with a silver spoon. In this condition washing out the soluble salts can be readily effected. Citrate of silver, which is formed in the foregoing reaction, is soluble in water, and as it is undesirable to remove this from the emulsion, only brief washes in two or three changes of water are admissible. This given, the excess of water is drained off, the shreddy pieces collected, rinsed in alcohol, and then melted, strained through fine cambric, spread on glass, paper, or any non-absorbent smooth white surface, levelled, set, dried, and printed. The remainder of the operations are washing, toning, fixing, and again washing the prints, as in the case of ordinary sensitised paper. Positives produced in this manner will tone well in a borax bath, and if paper prints are dried in contact with glass previously rubbed over with French chalk, will leave the surface when dry with a very high polish and considerable translucency.

Returning again to the collodio-bromide, we have here a process which yields some of the finest positives on glass obtainable by any method. Especially well does it answer for lantern transparencies, the inherent slowness being no drawback for such work.

A normal collodion, composed of a high temperature cotton dissolved in ether and alcohol, is bromised with a cadmium or ammonium salt, and another collodion containing silver nitrate is mixed therewith to form an emulsion of silver bromide. The solvents are then evaporated, and the soluble salt ammonium nitrate, the result of the reaction, is removed by washing, the pellicle is re-dissolved, and is then ready for coating glass surfaces. The emulsion is not suitable for printing right out, but is amenable to the influence of a developer. Alkaline pyrogallol is usually employed, but the ferrous-citro-oxalate developer recommended by Abney yields a perfectly black and vigorous transparent image, which can be toned by any of the recognised methods.

Following an analogous treatment here, and displacing collodion in this case, as we have already done in connexion with the chloride process of Simpson, we emulsify our silver bromide in gelatine instead of collodion by adding silver nitrate and soluble bromide thereto, and, as a result, get at least an equal speed. If by copious washing we remove the nitrate salt resulting from the reaction of silver nitrate upon a soluble bromide, some increase in the rapidity has taken place; but if we omit the washing, and alter the physical condition of the supporting colloid by setting up a decomposing influence in the gelatine—such as a high temperature, or the action of an alkali produces—a marked change at once sets in, but ceases upon the removal of the nitrate salt. The molecules of silver bromide as at first formed are pretty evenly distributed, and of equal size through-

out the mixture, and if a little of the newly formed emulsion were spread on glass, and examined by transmitted daylight, the film would be almost certain to appear red, especially if the precaution of slightly acidifying the gelatine has been adopted at starting.

It is impossible to preserve an emulsion in this state very long, neither is it desirable to do so. Decomposition sets in with liberation of free ammonia, and after the lapse of a few days, such an emulsion compounded without an antiseptic would have become perfectly putrid. In the meantime the silver bromide would also undergo a change in size and colour. An agglomeration of the molecules takes place, and the now coarse silver bromide, if examined by transmitted light, appears of a bluish grey.

Besides this slow method of altering the character of the silver haloid in the cold state, there is a plan by which the same effect can be brought about, namely, by the addition of free ammonia, either with or without the application of external heat, excepting that the emulsion under treatment must not be in a solidified state when the addition of ammonia is made.

There is also the most reliable plan of any for general practice, namely, heating or boiling the mixture until the desired change has taken place; but in either case it is beneficial to use only a minimum quantity of water, and the lowest proportion of gelatine capable of suspending the silver, the remainder being added when making up bulk before washing. In the process as given to the world by Bennett, the whole quantity of gelatine was subjected to a temperature not exceeding 90° Fahr.—for several hours to obtain a rather slow plate, and for days to acquire greater rapidity; but now the same result may be obtained in half an hour, provided the bulk of the gelatine which gives body to the film is added after sensitiveness has been gained.

When a thin film examined as referred to appears reddish, sensitiveness is seldom very great, but directly this has become changed, the maturing process need not further be prolonged. The point at which the ripening or gaining of rapidity is generally considered to have reached its climax for practical purposes is when a thin film of the emulsion spread on glass, and examined in the wet state by the plan already mentioned, appears of a bluish grey. Beyond this point there is considerable danger in continuing the action, as fog may intervene, and it is often really difficult to distinguish between exalted sensitiveness and foggy images in a delicately balanced dry plate. For this reason, perhaps, more than any other, the English makers of dry plates have a tendency to keep the speed of their ordinary plates down to fifteen or eighteen degrees by standard sensitometer test, rather than issue an emulsion of higher sensitiveness. Now, I presume most of us know that plates called *extra sensitive* are quoted by manufacturers at an increased price, but why this higher rate should be charged does not seem very apparent. Perhaps the truth is, that some rapid plates require more skill and judgment in order to attain a brilliant negative therefrom, whereas the slow plate possesses so much latitude that the liability of error is minimised to a large extent, and therefore the moderately slow plate is found to be the most successful upon the whole to popularise. It has over and over again been demonstrated that the actual cost involved in the preparation of rapid dry plates is but a fraction of the excess charged, and surely if it were a question of requiring two grains more or less of silver at 2s. 6d. per ounce to make it slow or quick acting, the difference now charged, I maintain, is excessive.

It is not necessary for me to quote particulars of plate making to-night, for it is a subject which would occupy your attention for a whole evening; and as the mere illustration of compounding a bromide emulsion now would not adequately demonstrate the process as it ought to be done before this Society, I will not attempt it, but any question which may arise concerning it in discussion I will do my best to answer.

In closing, I will just remark that the staining of silver bromide films, or the incorporation of certain dyes in an emulsion, to render the character of the sensitiveness more in harmony with some colours, is a subject which is of the greatest importance to photographers; but as we are told that to prepare such emulsions in England at present is not permitted by the proprietors of patent rights, except under special arrangement, I am afraid we shall not get a demonstration of making orthochromatic plates just yet.

W. M. ASHMAN.

PHOTOGRAPHIC USES OF URANIUM.

II.

THE salts of uranium were employed in the production of platinum images very many years since, but it does not appear that much beyond this stage of experiment was achieved. The learned authors of *Die*

Matinotypic say little on the subject further than quoting Nièpce de St. Victor's reputed "development" of the uranous image with solution of platinum, and Bollman's method of applying a mixture of uranium and platinum salts directly to paper and afterwards "intensifying." They observe that "the defect which qualifies every urano-platinum process is that the image obtained after exposure is almost invisible," and, further, "that the high price of the uranium salts will render the adoption of the process impossible in practice." I do not think the salts of platinum are readily reduced by uranous nitrate, which appears to have been the experience of Mr. Alleyne Reynolds; hence it may be inferred that the experiments of Nièpce de St. Victor were not successful and the reason understood. The difficulty attending the second process mentioned is one that Mr. Reynolds recently overcame in his platino-uranotype experiments by the use of an additional reducing agent, as in the iron-platinotype process, but there remains the question whether, as in the newest modification of this last process, the platinum, reinforced by a reducing agent, may not be applied to the uranous picture with success. Uranium chloride, oxalate, and nitrate, are not now higher in price than silver nitrate, and are amenable to being materially cheapened.

The action of light upon uranic nitrate has been found to correspond closely to the change undergone by ferric oxalate. The blue and violet rays deoxidise both salts; the red and yellow are inactive. It is further stated that the iron is affected by the green, and this degree, or rather range of sensitiveness is, I believe, also possessed by uranic oxalate. I am disposed to rank the uranic above the ferric salt in respect to the rapidity with which the positive impression on paper is received; in other words, the reducing action of the light takes place more quickly in the former compound. In comparing the uranous and ferrous images, if we set aside their basic characteristics, there is not, I think, a preponderance of photographic value in either. For rendering detail, for intensity and gradation of tone, they may be practically bracketed equal. There appears to me, however, greater risk of carrying the reducing action of light too far in the uranic than in the iron, in consequence, presumably, of what may be taken to be its relatively higher sensitiveness. An over-printed uranous picture can be well compared to a silver negative on glass, that has been seriously attacked by extraneous light before development. The over-printed uranous image is useless for further treatment. An iron image, if over-printed, tends to produce hard pictures, but is seldom prone to total loss of balance and vigour as in the analogous case.

The property possessed by uranous nitrate of depositing metallic gold and silver from their salts is, as of course every one knows, a characteristic of ferrous oxalate. Images in those metals, or in both united, are therefore feasible as a variation of the iron positive process. In actual application, however, this theory does not receive the most conclusive confirmation—I refer, of course, to my own experiences only. The protoxalate of iron easily reduces the gold and silver salts, even in the cold; but upon treating ferrous images with solutions of auric chloride and argentic nitrate respectively, acidified with oxalic acid, a reduction so quick and complete took place that the metallic deposits were insufficient to produce more than relatively weak images, although the amount of detail was considerable. I tried the effect of increasing the strength of the solutions with no compensatory increment of deposit. The ferrous oxalate, I take it, works in this instance with an excess of energy, and I am inclined to argue that by the employment of a restraining agent, the reaction would be less violent, and the deposition of metal would proceed with greater deliberation and evenness.

It may here, perhaps, be stated with advantage that those who at any time have the desire to undertake iron printing will find the preparation of the per-salt not difficult. Two methods of conducting it may be outlined. The ferrous salt is mixed with an alkaline carbonate, when a whitish precipitate of ferrous carbonate is obtained. This is boiled with oxalic acid until no more is dissolved, and the brown liquid decanted, filtered, and placed in the dark. Or ferric hydrate is prepared by adding to a boiling solution of ferric chloride caustic soda until it gives an alkaline reaction. The precipitate is washed until the alkalinity disappears, the water is removed and the iron hydrate mixed with oxalic acid and put in a dark place, when the formation of ferric oxalate will proceed and be completed in a few days. Ferric oxalate, however, is an article of commerce, and may be had of the purity requisite for experimental printing; while where it is sought to prepare the per-salt with the minimum of trouble the ferric hydrate is also obtainable. For very delicate operations, it will of course be necessary to determine the quantities of iron and oxalic acid contained in a solution of the per-salt.

The capabilities of ferric oxalate as an image-forming agent, and of the lower oxalate as a reducer, together with certain distinctive features of the salts of uranium, appear to indicate the possibility of

securing final pictures by the deposition of the latter metal. Metallic uranium, when isolated, is a dark coherent powder that is unaffected by the air at ordinary temperatures. In a test-tube reaction, cold ferrous oxalate dissolved in oxalic acid seemed not to reduce uranic nitrate very readily, and upon applying a solution of the latter and the acid to a ferrous image, this comparative failure was confirmed. However, by observing in the test tube the action of the ferrous solution upon uranic nitrate, with which a small proportion of gold chloride was associated, about 1:10, reduction took place. Upon applying the uranium-gold solution to a ferrous image the reaction was sustained, and a vigorous violet-black picture resulted. The half tones were deficient in delicacy, and the entire image had a coarseness inseparable from tentativeness, but of the practicability of producing positive impressions in deposited uranium and gold I was left in no doubt.

It is questionable whether the unchanged ferric salt exhibits an innocuous behaviour towards the uranium. A degradation of what should have been the white parts of the uranium-gold picture suggests that it is not inoperative, while on the other hand, from the failure to deposit plain uranium upon the ferrous image superadded to the apparent neutrality of the unaltered salt, it is open to assumption that the latter has no reducing power over the uranic compound. I am of opinion that the gold salt may be eliminated from the solution of uranium, and deposition of that metal alone effected on the ferrous image by, probably, the aid of heat and the substitution for the solvent of iron of a developing agent. But these and other points I reserve for the present.

As one is disinclined to publish formulæ that have not been tested by repeated experiments, I seek no justification for avoiding a semblance of practical details. Moreover, I have in mind a remark of the Editor that the field of iron printing is only partly explored, and it is in the humble persuasion that the same reservation is applicable to uranium printing that these notes are penned.

THOMAS BEDDING.

COMPARATIVE EXPERIMENTS WITH SODA, POTASH, AND HYDROQUINONE DEVELOPERS,

WITH EMPLOYMENT OF META-BISULPHITE OF POTASH AND VERY SMALL ADDITIONS OF CAUSTIC SODA AS A FORCER.

DURING the course of the month of November of last year, the accounts which were published in English, American, and German technical periodicals concerning the use of meta-bisulphite of potash caused me to make experiments with this preparation, for the purpose, on the one hand, of ascertaining how little hydroquinone one can employ, and, on the other hand, how much pyro or hydroquinone is necessary to preserve the "stock" solutions. As far as the hydroquinone is concerned, it was found that 0.4 gr. to 100 c.c.m. of developing solution was the smallest quantity which could be employed; if one uses less it exercises too restraining an effect upon the development. As many professional and amateur photographers employ hydroquinone, soda, or potash developers, and as these, as is well known, require always seven to eight minutes, I began to consider whether there was any preparation which could be employed as a forcer. I tried a small addition of caustic soda and caustic potash, i.e., 2 c.c.m. of a solution of 50 parts of caustic soda or caustic potash to 400 parts of water. The appearance of the first traces of the image was by this means considerably hastened, and the duration of the development very much shortened. The accompanying tables show the results obtained in the several cases. As regards quality, the negative appeared to be satisfactory and fit for use whichever of these various developers was employed; it became apparent, however, that the employment of caustic soda or caustic potash, in the case of soda and potash developers, produced more brilliancy and a greater clearness of detail, without considering that the duration of the development was shortened by several minutes.

Meta-bisulphite of potash restrains the development if employed in too large doses, but preserves the "stock" solutions much better than sulphite of soda alone. It is, however, advisable to dispense with the sulphite of soda, or to decrease its quantity in the formulæ, since the colour of the negative is thereby beneficially influenced. Meta-bisulphite of potash, in soda or potash-pyro developers, colours the negatives yellow, and sulphite of soda weakens this colouration considerably. The addition of bromide of potash, when this preparation is employed, is unnecessary.

These experiments induce me now to recommend the following developing solutions with hydroquinone, viz.:—

HYDROQUINONE-CAUSTIC SODA DEVELOPER.

Solution A.

Hydroquinone	10 parts.
Water	250 "
Meta-bisulphite of potash	4 "

Solution B.

Caustic soda	50 parts.
Water	400 "

Take for every 100 parts of water, 10 parts of solution A and 10 parts of solution B.

This developer acts very well for negatives, but not well for positives on bromide of silver emulsion paper, since the copies turn out very unequal in tone and mostly reddish in colour.

HYDROQUINONE-POTASH DEVELOPER.

Solution A.

Hydroquinone	10 parts.
Water	250 "
Meta-bisulphite of potash	4 "

Solution B.

Carbonate of potash	100 parts.
Sulphite of soda	50 "
Water	1000 "

Take for each development 10 parts of solution A, 50 to 75 parts of solution B, and 25 to 50 parts of water, according as a weak or strong developer is desired. To force the development add 2 c.cm. of caustic soda solution (50 : 400 of water); this addition has a beneficial influence upon the colour of the picture. For the development of positives, one may employ the same preparation.

HYDROQUINONE-SODA DEVELOPER.

Solution A.

Hydroquinone	10 parts.
Water	250 "
Meta-bisulphite of potash	5 "

Solution B.

Carbonate of soda	100 parts.
Sulphite of soda	50 "
Water	1000 "

For each development take 10 parts of solution A, and 50 to 75 parts of solution B, adding 25 to 50 parts of water. One is thus enabled to work with a weak or strong developer.

This developer, too, works much better when one adds 2 c.cm. of a solution of caustic soda (50 : 400 water). This preparation acts excellently for positives on bromide of silver emulsion paper, and is distinguished by the equality in tone which it produces.

It is advisable here to place the positives before washing in a weak solution of acetic acid, and to leave them a short time in it. Should the positives happen to be previously somewhat yellow, they regain by this means their whiteness.

The employment of bromide of potash as a restrainer is unnecessary, since meta-bisulphite of potash works sufficiently energetically. Since the addition of meta-bisulphite of potash, on the one hand, and of caustic soda solution on the other, worked so beneficially, I extended the experiments to the trial of soda-pyros and potash-pyros developers. Here, again, I found the meta-bisulphite of potash acted as a powerful restrainer; I attempted to prevent this by the addition of 2 c.cm. of weak caustic potash solution, and was agreeably surprised at the beneficial results I thus obtained. As no accounts of this procedure have hitherto appeared in the literature of the subject, the publication of it may perhaps prove of general interest. Even with these developers I would not advise the use of more meta-bisulphite of potash than I have indicated, since otherwise its influence is rather restraining.

It is further worthy of note that, as Professor Eder publicly declared, the preparation "Excelsior" which I introduced is highly effective in conjunction with the soda developer. The tables show this conclusively, while, on the other hand, it is true the preparation, when employed with the potash developer, does not act as a forcer or acceleratingly. Still, the other beneficial qualities that show themselves in the action of the "Excelsior" remain the same in both cases.

As is also shown by the tables, experiments were attempted with caustic potash, but as they gave less satisfactory results than caustic soda, and as the former is much more expensive, I recommend the use of caustic soda, more particularly as it is easier to obtain it pure. The caustic potash of commerce is said frequently to contain an amount of carbonate of potash.

At the conclusion of my paper, the series of experiments which were made public by Professor Eder in the December issue of the

Correspondenz have come under my notice. They agree remarkably with my observations.

As, however, I extended my researches so as to include experiments on additions of meta-bisulphite of potash and caustic soda, I venture to hope my readers will find them also of interest, for they are in reality merely a continuation of the same series, although carried out by a different hand.

EUGEN HIMLY, *Captain (retired).*

THE ACTINOGRAPH.

At a recent meeting of the Liverpool Amateur Photographic Association, Mr. V. C. Driffeld read a paper upon the actinograph, an instrument invented by Dr. Hurter and himself for calculating photographic exposures.

He said that one of the greatest difficulties the photographer has to encounter lies in correctly estimating his exposure. The fluctuations of the light throughout the year, and again throughout the day, are so great that they cannot be adequately allowed for unless some reliable data are at hand. Again, the great variety in the speeds of plates presents a very serious complication.

The actinograph is the outcome of an effort to reduce exposure to system, and to put the speed of plates on a satisfactory basis.

After many attempts Dr. Hurter succeeded in constructing an actinometer, which they believe to be the only existing means of rapidly and accurately measuring diffused daylight. One form of this instrument is self-recording, and for upwards of a year they took, by means of it, daily diagrams of the light, three of which were shown on the screen. From these diagrams they learnt that though the light fluctuates considerably, these fluctuations are limited deviations from a certain mean value.

In order to facilitate the calculation of exposures from the actinometer readings, they made use of a specially constructed logarithmic slide rule, and the actinograph is simply this slide rule with this difference, that the light value, instead of being ascertained from the actinometer, is ascertained from a specially constructed light diagram which records the mean value of the light.

A photograph of the instrument was here shown. It consists of a small box which can be easily carried in the pocket, and which contains, suitably mounted, four logarithmic scales, which correspond with the light, the lens, the speed of the plate, and the exposure.

The light scale is wrapped round a cylinder, and in contact with this is a slide bearing the lens and exposure scales, and fixed in a particular position is the speed scale. Sliding between the exposure and speed scales is an index pointing on the upper edge to five different exposures, and on the lower edge to the speed of the plate.

The light scale records the value of the light from hour to hour throughout the year by means of a system of curves, each curve giving the value of the light for a particular hour. The unit of light is so chosen that in places where the sun culminates in the zenith the bright test light is 100 units. One actinograph degree of light is, therefore, the 1/100 part of the brightest diffused light on the surface of the earth.

The lens scale allows for the differences in the construction of lenses, and for the various ratios of aperture to focal length.

The exposure scale indicates directly exposures ranging from 1/20 of a second to one minute.

The speed scale.—In speaking of this scale the author called attention to the pressing need of some scientific and satisfactory method of comparing the rapidities of different plates, and said that Dr. Hurter and he had endeavoured to meet this need by adopting as a unit of speed the length of time required to produce upon the plate a definite result. They call that plate speed one, which in one second, with one degree of light, produces under certain other conditions a satisfactory landscape negative possessing a certain definite ratio of density between foreground and sky; and a plate which yields the same result under the same circumstances in the $\frac{1}{10}$ part of a second would be said to be speed 100. The speeds indicated on the actinograph range from 0.5 up to 300. 0.5 is about the speed of a wet plate, and 30 is about the speed of the most rapid plate so far made.

The short scale sliding between the exposure and speed scales, and pointing on one edge to five different exposures, serves to allow for variations in the light due simply to atmospheric conditions. The single mark on the lower edge, termed the "speed index," is placed opposite the speed of the particular plate about to be exposed.

The author here made some remarks upon development. He said that it is popularly supposed that a great deal can be done in development to modify the effect of faulty exposure. Careful experiments made to decide the question, however, show that this control during development is, to say the least of it, greatly exaggerated. A technically perfect negative can only be produced by a correct exposure. The effect of abnormal additions of alkali is merely to hasten development, and eventually to fog the plate, and the effect of abnormal additions of a bromide is simply to retard development, and eventually to prevent it altogether.

The author proceeded to show, with the aid of the lantern, how correct exposures are calculated by means of the actinograph, and how the speed of plates is ascertained by the photographer himself. He also drew attention to the variations necessary in the light diagrams for different parts of the globe, several of which he exhibited. Actinographs are constructed for any latitude north or south of the equator at intervals of two and a half degrees.

BEAUMANOR AND CHARNWOOD FOREST.

THE outdoor meetings of our numerous photographic societies are, perhaps, the most enjoyable part of their proceedings, especially when the weather is favourable; but it was most aggravating during the latter part of May, preventing many members of the Derby Photographic Society from sending in their names to join the expedition of the 1st of June. Our destination was Beaumanor. The day turned out all that could be desired, save a little too much wind. We travelled by rail to Loughborough, where we found waiting for us a contingent of the Leicester and Loughborough Societies. We drove in brakes through the narrow streets, past the fine old church and comparatively new Grammar School and pretty cemetery, and were soon bowling along the old London coach-road.

Before reaching Quorn, of hunting renown, we turned sharply to the right, and trotted merrily up a lovely lane with overhanging trees and flower-besprinkled banks and hedges, and many a peep of the pastoral country on either side. The fresh wind from Charnwood Forest, laden with the scent of hawthorn, met us, and was very enjoyable, for the afternoon was hot and sunny, the sky a lovely blue dappled over with light cumulus clouds. Presently we came to a lodge embowered in trees and flecked with sunshine. We turn down the trim carriage drive soon to find ourselves landed at the south-east front of Beaumanor.

A host of cameras were soon rigged up, but only a few of our party tackled this view, for the sun was shining nearly in front of us and behind the building. The members soon dispersed in different ways, each one choosing his own pet subject. The horses were sent round to the stables to rest while we got hard at work. Many of us went to inspect and photograph an old coach, one of the lions of the place, and this was a great disappointment, for we found the lumbering, picturesque old thing of 1740 had had a special building placed over it, open at one side and one end, with huge brick pillars cutting into the view so that it could not be taken entire excepting a very much foreshortened view from the front. Three or four cameras were at work on this object, but we fear the results will not be very satisfactory. Wheeling it out into the light and free from the obstructions was out of the question—it was like a tortoise in its shell, and it is doubtful if its worm-eaten condition would have stood it either. Never mind, there were plenty of sweet pictures all around—a handsome, though modern house, a charming garden with grassy terraces and all the adjuncts that wealth and taste can supply, a pretty park with noble avenues of ancient trees, and freedom to ramble where we would and take away anything we pleased—on our plates.

Beaumanor is about four miles from Loughborough Station. The park is ancient, the fine Jacobean house modern (1847), and stands on the site of earlier structures. The last building was in the Italian style and of no great beauty. The first house here, dating from a remote period, was "moated round with a fair and clear moat"—it had a double moat in fact. Here came to reside Sir William Herriek, Elizabeth's ambassador to Turkey, to whom it was transferred by the celebrated Earl of Essex, who held it by lease from the queen. Since that time it has passed through the hands of seven or eight plain William Herrieks, for the

family has ever lived without ostentation, their motto "*Virtus omnia nobilitat*." The knight mentioned above was uncle and guardian to the celebrated Robert Herriek, author of the "*Hesperides*." We were shown some of the rooms, the noble entrance hall with its grand carved staircase and great stained window of glowing glass. Here we saw what must surely be the champion of chairs cut from the solid trunk of an oak which measured thirty-seven feet in circumference!

Now all had done and seen all we could, the party shouldered their cameras and wended their way through the park and the pretty little village of Woodhouse adjoining, where the same order and neatness prevail. The cottages are of the local stone of the forest, irregular pieces of slaty-looking rock of all colours, with pretty porches and gables. Climbing plants add to their beauty, and well-kept gardens, with many a lilac and laburnum, the background filled in with great trees, complete such scenes as we love to see reproduced on our magic plates. Only a few shots were made here, for was not tea ordered a mile further on at Woodhouse Eaves? Arrived there, however, we found so large a number was not expected, so we had to wait awhile; and the time was well spent in taking views of this picturesque part of the forest, the principal object being the church perched on a high rock with a yawning cavern at its foot. Many interesting rambles might be made from this village to Swithland, to Beacon Hill, Ulverscroft Priory, Bardon Hill, the Monastery, and other places of note in Charnwood Forest.

Tea ready, we filled two great tables and emptied them as well by next filling ourselves with the delicious ham and eggs—nothing like carrying a camera about to develop an appetite. Our brakes now came up from Beaumanor for us, and a return ride in the cool evening, with an enjoyable smoke on the way, soon brought us to Loughborough Station again, where each society had to part with promises of future meetings—the next one at dear old Haddon Hall. As we neared Derby the sunset sky was a revelation of beauty such as would have driven Ruskin into raptures. We cannot put that glorious scene into words, so we give it up. Here is Derby Station where we—stop!

RICHARD KEENE.

PHOTO-MICROGRAPHY.*

I use an excellent long-focus bellows camera made by Messrs. George Mason & Co., of Glasgow, the focussing screen end of which racks out, and not the front of it, which latter plan condemns a camera for the purpose of photo-micrography. This camera I always fasten with two screws to the platform of my bench, as one screw alone would not suffice to prevent lateral displacement, especially when the front of the dark slide is being drawn out. To prevent any vibrations of the dark slide containing the sensitive plate during exposure, I screw four stays of brass to the front and to the back of the camera, which stays are firmly screwed against two iron rails running alongside of the platform. In the place of the rising front I place a front having a wide square box attached to it, which contains a shutter for timing the exposure. The eyepiece end of the microscope body or the projection eyepiece is inserted through a round opening into the front of this box, and the light-tight connexion between camera and microscope is effected by means of a flanged tube, which is lined, and whose flange is faced with black velvet, and which slides over the body of the microscope. Now there is one very important, nay indispensable, adjunct to a photo-micrographic outfit, and one of which almost every camera should be possessed, especially those for copying or for photographing dimly-lit interiors, and that is, besides the ordinary focussing screen containing ground glass, one other such screen containing clear glass. It is needless to say that the inner surfaces of these focussing screens must register exactly with the film side of the sensitised plate. The light on the screen, when images under high powers are projected on it, becomes so feeble that these images are no longer visible through the ground surface, nor are they visible on the clear glass screen unless we place an eyepiece or an ordinary photographers' focussing glass upon it, which has its focus in the plane of that side of the screen which is turned towards the microscope. With this arrangement the image on the clear screen appears as distinct and luminous as it would if simply viewed in the microscope, and all difficulty about focussing under high powers vanishes. The clear glass screen serves simply as a support in the proper place for the focussing glass. A wooden screen with a number of holes for placing an eyepiece in it is sometimes employed for viewing the image, but this plan is not so good as the clear glass screen. Without such a clear glass screen all focussing with microscopical precision becomes mere chance work. There is another reason which often renders the use of a clear glass screen imperative, and that is when we photograph by monochromatic blue light in order to eliminate, as far as possible, any residue of chromatic aberration of the objective, and to increase its resolving power. The image in this case becomes far fainter than when projected by white light on the focussing screen. Monochromatic blue light is obtained by placing suitable blue glasses between the source of light and the object to be photographed, or a small glass tank filled with an ammoniacal solution of sulphate of copper, which solution must have been filtered; such a tank is often called the cupro-ammonia cell. The employment of monochromatic blue light is especially to be recommended for low powers which are not corrected

* Concluded from page 328.

for photography, because in these the differences of visual and chemical foci are greater than in the higher powers. These differences have to be ascertained by a number of trials for the different objectives, and have to be noted, so that the photo-micrographer knows in future how many turns of his fine adjustment the objective has to be withdrawn from the object after the sharpest possible visible image has been obtained on the screen in order to secure a sharp chemical image on the sensitive plate. Most modern objectives are corrected for photography, and in the apochromatics the visible and the chemical foci coincide, so that they give as sharp chemical images by white light as by monochromatic blue light.

I have now arrived at the last part of my notes, which deals with the *modus operandi* of taking photo-micrographic negatives, and which I purpose to illustrate by photographing a microscopical object. As I am addressing the members of the Glasgow Photographic Association, among whom are many of the foremost professional and amateur photographers of the West of Scotland, and as in the development of the latent image the same rules obtain as in copying or in any other branch of photography, it would obviously be out of place and presumptuous on my part to enlarge on this part of my subject. Should, however, any of my hearers not be acquainted with photography, and desire to give photo-micrography a trial, he will do well to get the late Mr. J. H. Jennings's little handbook on photo-micrography.

The illumination of the object having been carefully arranged, the table carrying the microscope is turned so that the axis of the latter coincides with the centre of the camera. I then raise three screws to support and fix the turntable, and make the light-tight connexion by means of the flanged tube. I focus next the image as sharply as possible on the ground-glass screen, and after that on the clear-glass screen, and shut off the light by means of the shutter in the camera front. This done, I insert the dark slide containing the sensitive plate, draw out the front, and after all vibrations have subsided, and the whole apparatus has come to rest, I make the exposure, observing during this time all possible precautions against the slightest vibrations. The exposure completed I close the camera by means of the shutter, push in the front of the plate carrier, and proceed to development in the dark room.

The length of exposure in photo-micrography is of quite the same importance as in any other branch of photography, and upon it depends chiefly the vigour of the resulting negative; but the latitude in the time of exposure by artificial light is relatively considerable. It is impossible to give any definite rule for calculating the requisite time of exposure, as this is influenced by many factors—such as the quantity and quality of the light; by its distance from the object; by the condenser, its focus, aperture, and position; by the thickness, nature, and colour of the object; by the objective, the eyepiece, and its distance from the screen; by the degree of sensitiveness of the plate used; by the nature and power of the developer, &c., so that there is here any amount of scope for exercising our speculative faculties, and any amount of chances of going wrong. Experience teaches one sooner or later to estimate the required time of exposure from the quantity and quality of the luminosity of the image on the focussing screen. Dr. E. C. Bousfield has published a brochure entitled *A Guide to the Science of Photo-micrography*, and in it is given a scale or table to find the time of exposure under different circumstances, and which table is based on the visibility of the figures on Warnerke's sensitometer under the same illumination and at the same distance from the screen as the gelatino-bromide plate, and used in conjunction with the known scale of the sensitiveness of the plates, either as stated by the maker or tested by the same sensitometer.

Regarding the choice of the plates, the wet collodion plate must be ranked as the first, judging from the results it is capable of yielding under proper treatment, but unless we can photograph by sunlight, the exposures, especially under high powers, become very much prolonged and often impossible. I have had to give, by lamplight, as much as half an hour's exposure when using so low a power as a one-inch objective.

use now only dry gelatino-bromide plates, preferring, of course, thickly coated ones, rich in silver, and of great, but not of the greatest, rapidity. I only use the slow plates when photographing with the lowest powers of the microscope, and when I aim at great density. Among the plates I have used most I can recommend the North British plates, owing to their great sensitiveness and the great density and contrasts they are capable of giving. I also use Paget's and Thomas's, but of late I have used many Ilford plates, which I have found remarkably uniform and good. Nor must I forget the isochromatic plates, which are especially serviceable when photographing objects with great actinic colour contrasts, such as blue and red, or brown. Dr. Roderick Zeiss recommends those of Perutz. I have also photographed on Eastman's stripping films with good results.

The developer to be used for photo-micrography ought to possess considerable latitude and power, such as those containing pyro and ammonia, but I prefer a developer containing pyro and a large proportion of sulphite of sodium, which is powerful and suits many brands of plates. In developing a negative one must not lose sight of the purpose for which it is intended, whether for printing positives on paper, or for lantern transparencies; for the latter the negative must be vigorous, leaving, if possible, the ground black. Negatives of photo-micrographs ought not to be retouched, as otherwise they might lose their scientific value and their character of truth. Intensification or reduction of the negative are, as stated already, the only changes permissible under certain circumstances;

the former enables us often to dispense with that difficult and wearisome process, the blocking-out of the ground by means of Chinese ink and black varnish, generally resorted to in negatives for lantern transparencies in order to obtain in the latter a ground of clear glass. As pictures, such transparencies may be very satisfactory, as the object photographed may be printed to any depth desired, but at the same time the clue to the thickness of the object is thereby lost, for the most pellucid object can be made to appear as possessed of great thickness and substance.

Regarding the size of the plates which are most suitable for photo-micrographic negatives, it is held that it is on the whole wiser to take sharp small negatives and quarter and half-plate sizes, and to enlarge these afterwards, instead of taking large direct photographs, if large prints are required.

As a photo-micrograph should possess all the detail which we can secure on one plate, it is obvious that for printing positives a smooth paper ought to be chosen instead of one with a rough surface. The making of transparent positives for the lantern is now a pleasant and easy task if we possess good and suitable negatives and such excellent lantern plates as Thomas's, Mawson & Swan's, Fry's, &c. No positive can, microscopically speaking, render all the finest detail of the negative, and in some cases it would therefore be advisable to show the latter on the screen instead of the former.

I have said nothing yet regarding the objects which may be photographed by the aid of the microscope, suffice it to say that comparatively few specimens or mounted objects will give good photographs, either in consequence of too great colour contrasts, or of unevenness of sections, or of uneven imbedding in the mounting medium, or of too great opacity, &c. Microscopical objects possess often very transparent, and, at the same time, more or less opaque parts apart from their colour contrasts, and so it is in such cases unavoidable that the transparent parts appear greatly overexposed, and the opaque parts greatly underexposed in the negative, and unless this defect can be corrected to some extent by the use of isochromatic plates, there seems no other way out of this difficulty. Live objects have to be photographed by the use of the so-called instantaneous shutters and a powerful light. In this case a finder will be found extremely useful, which is a separate microscope body carrying an eyepiece, into which the image is reflected by means of a small prism, so that the operator can seize the favourable moment when the moving object is in the field of view.

With these remarks I bring my notes to a conclusion, trusting that they may induce some of you to begin and pursue photo-micrography, and that they may assist others practising this most useful and fascinating branch of photography already in overcoming some of the difficulties besetting their path.

ADOLF SCHULZE, F.R.S.E., F.R.M.S.

After Mr. Schulze had read his paper, he photographed the proboscis of a blow-fly on an Ilford half plate, and subsequently showed some sixty lantern transparencies of microscopic objects by means of the limelight on the screen. These transparencies Mr. Schulze had printed from his negatives, and the subjects embraced botanical, entomological, and physiological specimens, crystals, minerals, and starches photographed by polarised light, and a number of beautiful diatoms photographed under high powers.

CURRENT COMMENTS.

SHADOWLESS MOUNTS.

In a recent answer to a correspondent, in which F. R. Fisher wishes to know how to avoid shadows with cut-out mounts under glass on photographs mounted in optical contact on glass, your answer is, "It cannot be done." I think it can. Try it in this way:—Do not use a purchased cut-out mount, but, rather, take a good mounting board of the shade you wish, and of any thickness up to "twelve-sheet" (the thicknesses are given always in sheets, although they may be pulp boards), and cut it to size and shape, but instead of cutting the bevil at the angle of from 45° to 75°, as is usually the case,—

make the bevil at a much more acute angle, say from 20° to 25° from the horizontal line,—

This, if skilfully done, will, it will be seen, thoroughly obviate the cast shadow given by the steeper bevils most usually adopted in the "manufactured shop mounts."

ORTHOCHROMATISM versus COLOUR SCREENS.

Like our old friend, "Free Lance," I have tried the interposition of coloured screens in almost all kinds of ways, but as I do not remember having seen some of the methods adopted put on record, they may be explained as being useful and easily accomplished, and probably they will

be new to many. There are now to be got in the market brown paper tubes of all sizes, but if they can not be easily got they are very simply made by pasting the paper round a mandril of the proper size and leaving it till dry. Make or get one just the size of the cap of the lens which is being used both in diameter and length, then take a piece of stout mounting board of rather larger size than the external diameter, and on this draw a circle slightly smaller, say one-fourth of an inch all round, which cut out and smooth on the inside edge of the opening, then square and glue the brown paper cap on this, keeping an equal margin all round. When dry, cut off and smooth the spare mounting board and smooth it off neatly, then give it a coat of dead size black, or stain it with ink, or blacken it in any other convenient way, and, when dry, having your sheet of coloured gelatine (this can be had in almost every colour) ready, slightly damp the annular ring which will be in front of the cap and press it on the gelatine, straining it so that it is left quite tight and flat. This will give a transparent cap for the lens of any desired colour to be used as a colour screen.

Another way, and a very handy one for experimental purposes, is to make a similar cap, but keeping the outside size of the mounting board considerably larger, in the shape of an oblong square, and on the top and bottom edges of this form with strips of mounting board, of the proper thickness, a rabbet and cheek kept sufficiently loose to allow pieces of coloured glass to slip along easily, just as lantern slides do. It will be easily seen that by this method any kind of transparent screen of coloured glass, or of plain plate glass, with collodion tinted to any shade by such of the coal tar dyes as are soluble in spirits of wine, can be used and experimented with.

The latter form of cap was found to be by far the handiest, as any and every shade can be tested with the ordinary plates as against orthochromatic ones for the same class of work. They have been so tested, and some day a careful note and analysis may be ventured upon for the benefit of your readers.

BICHROMATE POISONING AND DISEASE.

As an aid to the further knowledge of this, perhaps the record of a severe case, the particulars of which I personally was acquainted with, may be of some use. The late Mr. D— was a keen experimenter with the carbon printing process when first introduced, and as he was nothing if not thorough, he did every portion of the work with his own hands until he was master of the work. Unfortunately for him he was either a good subject for attack, or the insidious particles passed more easily through his skin than that of others similarly engaged, but so it was. He began to be troubled with what he thought to be psoriasis, but by consultation with his medical adviser he was induced to think it one of the forms of eczema, and underwent the usual course of treatment for this painful and annoying disease, but it was all of no effect. The drying of the skin, the bran-like scales, but not the red rash, were all there, but in many cases the scales were red and painful. It extended even to and over the eyes, and this continued for many months, till it, in addition to being unbearable, was thought to be incurable. Utterly incapacitated for business, he was early induced to try some of the German spas and baths, and while doing so consulted several of the most eminent physicians of that country, but with little effect, till one of them made a bold guess at the bichromate as the cause of the malady, and by judicious treatment for this he was ultimately cured. The bichromates were not then used so largely, or their qualities so well known. The case lasted over eighteen months.

W. H. DAVIES.

CAMERA CLUB CONFERENCE PAPERS. THE LIMITS OF PHOTOGRAVURE.

By A. DAWSON.

HAVING been desired to prepare a paper on photogravure—i.e., the production of intaglio plates in half tone (although line subjects and maps are equally photogravured)—I desire to respond to the best ability that other demands will permit.

I propose in this paper to keep to the artistic aspect of the question, and so doing rather to point out the limits of the science as I have so often encountered them. Others, I am aware, frequently take a sort of pride in the capabilities of the method; but when the demands of taste have to be met, it does not allow one much time to think of anything but how to enlarge our field of work, and how to increase our production without losing quality. Remembering that well-cut copper plates never gave the number of impressions that were desired by engravers, and that steel plates were introduced to remedy this defect—then remembering that photogravure plates are far weaker and shallower than even copper engraved plates—it will be seen that there was much to be done, and there still is much to be done, to make it perfect. I would suggest that the making of a fine photogravure in steel be kept in mind as the desideratum of the future.

Of course, we steel-face all plates nowadays, however engraved, so only that they are made of copper. But any one who has had to work a plate hard knows the grief of wearing the precious film of iron (or, as it is called, steel) away. This protecting coat is the only thing that makes photogravure a possibility for book work; and the wearing of it away is

the one great hindrance to the long endurance of the plates. Partly by reason of the action of solvents in removing it, partly by incipient wear when it gives way, the second coat of steel is found always a greater load for the plate to put up with than the first—lights are smoother and darks are more levelled down to one uniform shade. This power or endurance of the first coat of steel then becomes the real limit of the number of fine first-class prints obtainable. The art of making a really good and yet thin steel face carries a deal along with it. We generally reckon 500, but often 1000 are printed off one facing before it gives way.

It is rather hard to have to start in this tone, but it is really necessary to remove the common impression that once a copper plate is manufactured an infinite number of the finest impressions can be produced as a matter of course. It is a great mistake in the present condition of the art.

Let me now imagine a plate from Turner's *Liber Studiorum* before you, and I would say that, putting aside the enormous power of the bitten outlines, the mellow transparent tones are what we have to get. Remember that these plates are deeply cut into the copper by the mezzotint tool, which cuts sharper and deeper than holes made by chemical means. The result is that a transparent ink made with soft colour, such as bitumen or Vandyke brown, may be used instead of black and burnt umber. The result is that the deep plate gives a much softer and more glowing print than we do with our shallow chemical grains.

I do not think I can by all my power convey to an ordinary onlooker an idea of the great width and depth of the gulf that once separated the struggling processist from the technically perfect engraver in steel or copper. I feel sure that if the processist knew the length of the journey before him he would scarcely have desired to start on it.

But, instead of this, we found the first photogravure or the first relief photo block, swaggered about and shown all over the plate as a wonder and a thing to supersede the hand entirely. Now, although the automatic methods are at present very much to the fore, yet it is chiefly as rivals. Etching has made giant strides beyond all our early anticipations; scientific skill and cultured taste have placed wood engraving quite on the platform of a fine art. The result is that, although processing is a truculent and ever-watchful rival, it is kept in a limited field; and whether in relief or intaglio, I am quite sure that human mind and skill, having brought one branch out of nothing, will bring the other out of past shortcomings to future excellence undreamed of now.

The same spirit of swagger followed the first good results of photography, and what do we find now?—simply that it is a serviceable assistant to art; but no artist building up the feeling of a composition bit by bit, line by line, tone by tone, with centuries of work and the labour of great genius piled together on his mind, can ever get more than a suggestion from it. It is certain that the photograph is a useful help, but it is no substitute for art. So it is certain that photogravure is a useful means of producing prints—probably the best means devisable for making a high class facsimile; yet the artist is as careful as ever, and the man of science will wait upon the artist, and the artist will help the man of science. Thus the earlier idea of superseding and abolishing an old art must be given up, and a new idea of co-operation to a single end take its place.

I go through these points at some length because they are the result of my own laborious and energetic efforts to produce art by processing. Year after year the attack has been renewed, but though processing has advanced, it has been apparent that the goal advanced also; and that, though I could do things easily that the hand could never do so truly, yet that same hand guided by skill and taste did things that I could never catch up by my processing.

Perhaps the prettiest point in photogravure has been its power to render the texture of the surface of the picture or original. It is peculiar that in proportion as a copy without texture is employed, such as a silver print, so in proportion does it become difficult to make a plate that pleases the eye. If, however, instead of the silver print we use the negative from which it was printed, we get a much better result—chiefly in this case, I believe, because the print on paper is a defective original compared with the negative, its tones being less accurate, and its outlines being a little furred up by the fibres of the paper.

But if we make a plate from a rough wash drawing, it is quite pleasing to see the rough paper texture. Now take a silver print of this rough paper sketch, and it immediately looks poor in comparison. We now see that the photogravure is capable in things where the photograph is weak, but the photograph is strong in the brilliant, yet tender, reproduction of natural forms, portraits, &c., though its very smoothness and perfectness unfit it for many purposes of art reproduction. This being so, it will be well to push each art along the line that it has shown a power over, and not to strain too much after things that it cannot do.

(To be continued.)

SHAFTESBURY PHOTOGRAPHIC SOCIAL.—On Friday (this evening), at half-past eight, Mr. Baker will give a paper on *Lantern Slide Making*. Visitors invited.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The last ordinary meeting for the season will be held on Tuesday next, June 11, at eight p.m., at the Gallery, 5A, Pall Mall East, when matters of interest will be brought forward.

Foreign Notes and News.

THE Society for the Promotion of Photography in Berlin has recently been having a good deal of discussion about the origin of black rims in dry plates. According to Herr Stoll, the employment of soda as a finer was to some extent to blame, but he was more inclined to lay the trouble at the door of the paper in which the plates were packed. Herr Vogel attributed the cause to the action of sulphurous acid liberated by acids contained in the paper.

THE same speaker then proceeded to give an account of his experiments with paraphenyl diamine, which he did not find give as good results as its patentee claimed. Herr Stoll made the experience that the addition of small quantities of caustic alkalies improved the action, although clouding was easily produced thereby.

THE Berlin Society of Friends of Photography admits ladies as members, and at its recent general meeting elected by ballot four young ladies, all of whom are Berlin artists.

HERR SCHIRM, of Breslau, made some observations concerning the employment of the magnesium light. He says that it is inadvisable to have the tubes, through which the magnesium powder is blown, too long, as the powder is liable to remain hanging in them, and so to arrive too late in the flame. The best thing is to blow it in quite close to the flame. The flame itself ought to be as open as possible, as otherwise some of the powder passes off unburnt. An oxidising flame, particularly that of a Bunsen burner, works remarkably well. A very small amount of magnesium is required, 1½-2 centigrammes usually sufficing for each lamp.

HERR VOGEL exhibited some plates made by Dr. Baekeland, which on being immersed in water developed themselves, the substances required for the development (soda and hydroquinone) being spread on the back of the plate. As the front side of the plate often gets soiled with some of the preparation from the back, causing local reduction and injury of the photograph, Herr Vogel recommended that the developing substances should be employed in the form of bulbs or small cartridges.

THE same gentleman pointed out later that grey hydroquinone acts just as well as white, as the colouration is only superficial. He further drew attention to the fact that the new "permanent hydroquinone" of Dr. Byk occurred in commerce in yellow crystals, often containing traces of sulphurous acid, and that it may be employed with just as good results as the other.

THE teachers in the Photographic School of Hanover give at present an excellent example of devotion to the science, inasmuch as they fulfil the office of imparting instruction to a number of pupils and apprentices without any kind of remuneration.

THE recent meeting of the Silesian Society of Friends of Photography, which took place in Breslau, appears to have been illustrated by some rather interesting exhibits. Amongst other objects were displayed a very artistic and interesting collection of a large number of photographs of Italian antiquities—ruins, grottoes, &c.—taken in the open air with picturesque backgrounds; further, a collection of landscapes on platinum development paper, showing the great advantages of development paper over ordinary copying paper, especially as regards clearness and definition of the shadows; a very good series of flash-light impressions of subterranean buildings completed the exhibits.

A GERMAN tribunal has decided that in a case where an action was brought to restrain certain persons from reproducing a photograph by lithophany, such reproductions came under the category of graphic reproductions, and that consequently it was not permissible to reproduce pictures or photographs without the permission of the holder of the copyright. The defenders maintained that lithophany belonged to the plastic arts, and was, therefore, beyond the scope of the law respecting the issue of unauthorised counterfeits.

THE only photographic periodical in the Hungarian language, the *Fényképeseti Lapok*, published by Franz Veress, of Klansburg, finishes its seventh year with the present number, which contains an intimation that for lack of support it will hereafter cease to appear.

AN interesting communication has been made to the Société Française de Photographie by M. Grassin, of Boulogne-sur-Mer. He succeeded in developing an instantaneous plate which had been exposed more than two years previously, and found that during this long period it had not lost any of its quality.

PATENTS COMPLETED.

IMPROVEMENTS IN AND RELATING TO PHOTOGRAPHIC SHUTTERS.

No. 6583. HARRY WILLIAMSON TEEB, 188, Camberwell-grove, Camberwell, Surrey.—May 3, 1888.

My invention relates to shutters for photographic cameras and the like, and to mechanism for actuating the same.

According to one part of my said invention, I provide a shutter for a photographic camera by means of which the amount of exposure given to the sensitive plate or film, or any part of it, can be easily and expeditiously regulated.

My said invention comprises moreover various other improvements hereinafter set forth.

In carrying my said invention into practice, I prefer to provide a shutter formed in two parts or portions, that is to say divided vertically in the centre of the same. The said shutter may be of a circular or other suitable form when closed, and is provided with any suitable joint where the two parts of the said shutter meet, so as to exclude the passage of light through the same. I provide moreover the said shutter with extensions or prolongations pivoted to any suitable part of the apparatus. The said extensions or prolongations of the shutter are fitted with pins or projections adapted to work in slots in a suitable plate arranged to slide in V grooves or in any suitable manner in guides also attached to any convenient part of the apparatus. The said slots are formed curved, so that the extremities of the same are in proximity to each other in the above-mentioned plate, and when the said pins are at either extremity of the said slots the shutter will be in a closed position. The said plate is also provided with a pin or projection adapted to engage in a slot in the extremity of a lever attached to a suitable spindle pivoted to any convenient part of the apparatus. This lever is provided with a spring, which acts upon the said lever so as to tend to keep the latter constantly depressed, that is to say in its closed position, and thus to maintain the hereinbefore-mentioned slotted plate normally at one end of its stroke, the pins or projections being at the upper extremities of the slots. The spindle of the said lever projects through the case of the apparatus, and is provided with a handle, by means of which the mechanism of the apparatus can be set or cocked, as hereinafter described. The said handle is moreover provided with a pointer adapted to indicate upon a suitable dial when the said mechanism is set or cocked. To set or cock the said mechanism, I provide a lever pivoted to a bracket attached to the guides carrying the hereinbefore-mentioned slotted plate. The said lever is provided with a suitable spring, and has a shoulder or projection adapted to engage with the hereinbefore-described pin or projection upon the slotted plate, and thus maintain the latter at the top of its stroke, and the pins or projections at the lower extremities of the said slots. The said lever is moreover provided with an extension arranged to act in connexion with any well-known pneumatic device, by means of which the said lever can be actuated so as to release the hereinbefore-mentioned pin or projection upon the slotted plate from the shoulder or projection upon the said lever, and allow the said slotted plate to descend to the bottom of its stroke. During the descent of the said slotted plate the parts of the shutter are opened by the pins upon the extensions of the said shutter passing round the hereinbefore-described curved slots, the shutter being completely open when the pins are at the greatest distance apart in the said slots. Instead of employing a pneumatic device to actuate the hereinbefore-described lever, I sometimes cause the extremity of the said lever, or an attachment to any part of the said lever, to extend through the case of the apparatus so that the slotted plate can be released by operating the same.

In some instances moreover I provide a time limit, so that the duration of the exposure can be regulated to last for any predetermined length of time. To accomplish this object, I provide a suitable train of clockwork mechanism, which can be wound from the outside of the apparatus by means of a convenient handle, a pointer being also provided to indicate upon a suitable dial the duration of the exposure.

I moreover provide means for starting the said time limit, comprising a lever arranged to be actuated by the slotted side when the latter is at the beginning of its stroke. The said lever is thus caused to bear against a spring or pawl and cause the latter to engage with a toothed ratchet or other wheel and thus allow the time limit to be employed. Underneath the hereinbefore-described lever engaging with the pin or projection upon the slotted plate, and pivoted to the same bracket attached to the guides of the latter is another lever, or inside lever, provided with a pin or projection bearing against the first-mentioned upper or outside lever, and with a suitable spring adapted to cause the said lever to follow the movement of the said upper or outside lever. The said lower or inside lever has at its lower extremity a projection or hook adapted to engage with the hereinbefore-mentioned pin or projection upon the slotted plate, and retain the same in such a position that the pins or projections upon the extensions of the shutter are at the greatest distance apart in the said slots, and therefore the said shutter is in its open position. The said shutter is retained in this position until the time limit (which has been released by the partial descent of the slotted plate, releasing the lever and pawl hereinbefore mentioned) unlocks the said inner lever by a projection upon the said toothed or ratchet wheel, or any suitable toothed or other wheel of the clockwork mechanism impinging against an extension of the said inner lever and tilting the same, when the shutter instantly closes. Or the said shutter can be closed at any time during the operation of the said time limit by releasing the upper or outer lever.

I prefer to employ moreover a suitable catch adapted to engage with the hereinbefore-described pointer, and thus lock the said time limit and prevent it from operating when not required. I can, however, employ any other convenient means for this purpose.

When the said time limit is locked, by setting or cocking the hereinbefore-described mechanism, the shutter can be opened and retained in that position at will by actuating the pneumatic device, or by operating the mechanism by hand.

I sometimes moreover provide a cam capable of being moved from the outside of the case of the apparatus and adapted to bear against the hereinbefore-mentioned pin or projection upon the inner lever, and thus actuate both the

inner and outer levers. The shutter is thus opened and will remain in that position until the said cam is again moved out of gear with the said pin or projection.

The above-described shutter can be placed either before or behind the lens or lenses, or it may in cases where a combination of lenses are employed be placed between the said lenses.

Moreover, in some instances I provide a hood or screen, composed of any suitable substance, so as to give a greater proportion of light to one part of the sensitive plate or tissue than to another; as, for example, to give the full amount of exposure to the foreground, but a less proportion to the sky. To effect the above object, I prefer to place a hood or screen, of such a form or shape in the passage of the light as to abstract the required proportion of the rays travelling to any part of the said sensitive plate or tissue. The sky may be thus deprived of any required proportion of light in a uniform or varying degree. The above-described hood or screen is placed either in front or behind the lens, and is so arranged as to be capable of adjustment to any extent required. Either one or more of the said hoods or screens can be employed.

Although I have hereinbefore described a convenient and advantageous method of carrying my said invention into practice, it is obvious that I can modify the construction of my apparatus without, however, in any way departing from the nature of my said invention; and, moreover, that a portion of my said invention, that is to say, the hereinbefore-described mechanism for instantaneously opening and closing a photographic shutter, the time limit, the means for retaining the said shutter open at will, and the hereinbefore-described hood, are applicable to drop shutters, revolving shutters, hinge shutters, or photographic shutters of any other description.

IMPROVEMENTS IN PORTABLE PHOTOGRAPHIC CAMERAS.

No. 9327. PETER CHARLES, 26 and 27, Milk-street, Cheapside.—
June 26, 1888.

THIS invention relates to improvements in portable cameras intended for use in instantaneous photography, but also applicable for employment where a long exposure is allowed. A camera constructed according to this invention is specially adapted to fulfil the requirements of detectives.

The body of the improved camera consists of a rectangular box, having in front a screened aperture for the reception of the lens, and provided at the top and bottom with sliding lids for the admission of unexposed plates and the withdrawal of plates that may have already been exposed. The said rectangular box is formed with a central horizontal partition, over which slides a receptacle containing two compartments arranged one above the other, the said horizontal partition forming the division between these two compartments. The upper compartment is adapted to contain a series of unexposed plates arranged parallel with and in close proximity to and behind one another. Each plate is backed by a darkened sheet, or may, if preferred, be mounted in a frame provided with a darkened back; these sheets or frames being by preference of metal, and serving as screens to prevent the passage of light. Each plate, after exposure, is permitted to fall, through a slot in the said horizontal partition, into the lower of the two compartments, the plate receptacle; the said slot being normally covered by a spring-actuated slide operated when it is desired to permit an exposed plate to fall by means of an external hand lever. The sides of the plate receptacle are formed with a series of grooves for the reception of the several plates; the lid of the same is likewise grooved, the top of each of the plates lying within one of the grooves, the passage of luminous rays to any unexposed plate or plates being hereby further prevented. The plate receptacle is fitted at the bottom with a rack engaging with a pinion mounted in the body of the camera. The pinion is turned by means of an external button or finger-piece, the plate receptacle being thus caused to slide within the body of the camera in either direction, according to whether it is desired to charge or empty the same, or to bring the unexposed plates successively into the proper position for exposure. The latter end is easily accomplished by forcing in turn each unexposed plate against a suitable stop or stops provided for the purpose. An indicator is fitted at the side of the camera for denoting the number of unexposed plates remaining within the plate receptacle.

The lens, if moveable, may be actuated by means of rack and pinion mechanism. In its normal position it is arranged so that all objects beyond a given distance, say twenty feet, may be in proper focus. When the lens is adjustable an indicator is preferably provided outside the body of the camera in order to show the proper positions for different distances.

A revolving shutter is employed, rotating, by preference, behind the lens and mounted upon a horizontal spindle formed or provided with a pinion adapted to engage with a toothed driving wheel driven by a coiled spring. The latter is wound, as occasion may require, from outside the case by means of a key or handle. The shutter is held and prevented from moving until the proper time by a pivoted catch operated by means of an external finger-piece. The said pivoted catch is preferably furnished with a tail-piece adapted to engage with the shutter after the latter has rotated the requisite distance; the said tail-piece being disengaged and the catch again thrown into action when the finger-piece is returned into the normal position. Brake mechanism is employed for the purpose of regulating the speed at which the revolving shutter is permitted to rotate. Such mechanism may comprise a leather disc mounted on a shaft carrying a pinion engaging with the toothed driving wheel, a spring bearing against the said disc. The pressure exerted by the said spring may be regulated by means of a cam or a screw, an indicator being provided on the cam shaft or on the screw, in order that the brake mechanism may be adjusted to permit the shutter to revolve at the proper speed. For a slow exposure a special and independent catch is provided, which, when in operation, holds the shutter in such a position that the aperture, or one of the apertures therein, is immediately behind the lens.

The camera is furnished with suitable view-finders, and means are provided for enabling legs or supports to be attached when desired.

The claims are:—1. The improved construction of a portable photographic camera arranged and operating substantially as set forth.—2. In a photographic camera, the employment of a revolving shutter actuated by a coiled spring adapted for the storage of sufficient power to operate the shutter repeatedly, according to the number of plates to be exposed.—3. In a photographic camera,

a shutter arranged to revolve in one direction only, and driven by a coiled spring, the rotary movement of the shutter being controlled by a catch, substantially as set forth.—4. In a photographic camera, a revolving shutter provided with brake mechanism for enabling the speed of rotation to be regulated, substantially as described.—5. In a photographic camera, the combination, with a spring-driven shutter arranged to give a series of successive exposures, of a plate receptacle containing a series of plates for successive use, substantially as set forth.

IMPROVEMENTS IN MAGIC LANTERN SLIDES.

No. 3340. WILLIAM CHARLES HUGHES, Brewster-house, 82, Mortimer-road, De Beauvoir-town, N.—March 5, 1889.

MY invention has for its object the covering of the edges of magic lantern slides and the like with thin sheet copper, brass, or other ductile or malleable metal, in such a manner as to more perfectly protect the edges of said magic lantern slides than if covered in gummed paper or braid, as heretofore, which is liable to get roughed up and broken away after a little use.

In carrying out my invention I may either use a narrow strip of suitable metal of troughed or channelled shape, with pieces cut out at intervals corresponding with the width of the slide to be covered, thus allowing it to be bent round the edge of the said slide without creasing, or I may take a square piece of sheet metal and cut therein a central hole of the size required, and at a pre-determined distance from said aperture turn up the edge of the metal all round, previously cutting the four corners in such a manner that the edges of the sheet metal can be pressed over the edges of the slide without creasing.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

MAY 30.—Mr. T. Kerr in the chair.

The Hon. SECRETARY announced that he had been trying Dr. Liesegang's Pizzighelli platinum paper, and he exhibited results which he had obtained by half an hour's exposure to sunlight under a negative; he had found the printing to be quicker than with some other papers of the class which he had tried; the pictures were flatter than ordinary albumenised prints from the same negatives.

Mr. F. P. CEMBRANO had worked platinum processes extensively, and, by direct comparison of results, had found the old processes by development to be superior to the new ones in which the photographs are printed out.

Mr. A. COWAN stated, as already published, that he had found bromide of ammonium in the quinol developer to produce a yellow stain in the negatives.

Mr. CEMBRANO said that under-exposed plates gave a yellow stain with quinol.

The Hon. Secretary exhibited a silver print on tissue paper; it was five or six years old, and presented no signs of fading.

Mr. W. E. DEBENHAM always washed his silver prints in several alternate changes of hot and cold water; the hot water was as warm as the hand could comfortably bear.

Mr. H. D. ATKINSON asked how in photographing from the top of the Eiffel Tower the lines of buildings could be kept vertical.

Mr. DEBENHAM replied that if the plate were kept vertical the lines were bound to be vertical.

Mr. CEMBRANO wished to know whether cloud negatives taken at the seaside required less exposure than cloud negatives taken far inland, all other conditions being equal; he had reason to suspect that such was the fact.

Mr. COWAN suggested that the sea might reflect light upwards.

Mr. W. H. HARRISON remarked that inland there might be more floating dust in the air, and that would tend to cut off the violet more than the less refrangible rays of the spectrum.

Mr. CEMBRANO had found that immediately after sunset the exposures must be increased enormously to get cloud negatives; with extra rapid plates he had given exposures of eight seconds with an *f*/64 stop.

UNIVERSITY COLLEGE PHOTOGRAPHIC SOCIETY.

MAY 28.

A paper was read by Mr. J. T. LEON, B.Sc., F.C.S., on *Direct Printing Processes*. The author began by giving a short description of the Daguerreo-type process, and showed some exceedingly beautiful examples. The Calotype process of Fox Talbot was then described, consisting of taking a picture on paper coated with iodide of silver and washed over with gallic acid, and finally developing in a similar solution of gallic acid. This process has much to recommend it even in the present day, on account of the few solutions and apparatus required, and especially in hot climates. The next method described was the preparation and printing of ordinary albumenised papers. The necessity of having free silver nitrate in the paper was shown, and also the use of the organic compound. Prints were shown on a matt gelatine paper, and the

author recommended matt-surface papers from an artistic point of view. The operation of toning was then discussed. The author considered that the object of a toning bath is first of all to bring the gold as near to reduction to the metallic state as possible. This causes the attraction of the silver, or subchloride of silver, as the case may be, to chlorine to be greater than the attraction of the gold; therefore gold is deposited instead of silver, and silver chloride is formed. This chloride is finally all removed in the fixing bath. In his *Treatise on Photography*, Captain Abney gives various complicated reactions for toning with various baths, and those in the case of the acetate bath were given as an example. The author considered these to be quite unnecessary according to the simple theory given above, and also thought it most probable that the salts mixed with the gold chloride only tended to prevent the bath getting acid, though he considered this the only point upon which one could not speak with certainty. Toning with platinum was then mentioned, and prints shown toned with platinum, according to the method described by Mr. Lyonel Clark in *THE BRITISH JOURNAL OF PHOTOGRAPHY* for April 12 last. This method was much recommended. Printing with salts of iron was then discussed. The action of light on ferric salts is to reduce them to the ferrous state. Cyanotype—the method of printing a positive from a positive—was then described. If printed from a line drawing, the first of these would give blue lines on a white ground, and the second white lines on a blue ground. The difference is easily understood if it be remembered that ferrous salts give a blue precipitate with ferricyanide, whereas ferric salts only give a blue precipitate with ferrocyanide of potassium. The only other substance mentioned was uranium, the uranic salts being reduced to uranous by light, which may be developed by ferricyanide of potassium, and also gold, silver, and platinum. Examples of each were shown. Paper coated with salts of iron and exposed to light can also be developed by any of these means, as in the platinotype process.

On Saturday, June 1, the Society made an excursion to Epping Forest.

At the next meeting, Tuesday, June 11, Mr. E. S. Warrall will open a discussion on *Exposures*.

MANCHESTER PHOTOGRAPHIC SOCIETY.

ABOUT twenty members and friends of the above Society spent a very enjoyable afternoon at Gawsworth on Saturday afternoon last. Leaving Manchester by the one o'clock train, Macclesfield was reached at fourteen minutes to two, where a large brake awaited the party. A pleasant drive of over three miles brought them to that photographic gem, the old Perpendicular Church of St. James's, Gawsworth. Cameras were soon at work, both on the interior and the exterior, and the fine old Rectory and the old Hall each had their full share of attention. After tea, at the Harrington Arms, the return to Macclesfield by a fresh route was accomplished, and the party landed in Manchester, completing one of the pleasantest trips of the season.

BATH PHOTOGRAPHIC SOCIETY.

MAY 29.—Mr. Philip Braham, F.C.S., presided.

Mr. F. W. Simpson was elected a member of the Society.

The pictures taken at the outdoor meetings of April 25 and May 23 were then shown. The first outing was at Farleigh Castle, a pleasant ride of nine miles from Bath. The old chapel, ruined gateway, and various other spots were photographed from different points of vantage. The second outing was to St. Catherine's Court, a beautiful house and grounds, part of an old monastery in the picturesque valley of St. Catherine's. The results were highly satisfactory. That the Society is making rapid progress may be judged from the fact that about two dozen members attended the outdoor meeting, and the Bath society paper, *Blatant*, in noticing the work done, remarked on the great success of the undertaking in Bath.

The Hon. Secretary showed his negatives of Farleigh Castle treated with different developers—hydroquinone, pyro and ammonia, potash, soda. The general feeling was in favour of potash.

Mr. W. M. Ashman also exhibited, on behalf of Captain Molesworth, a series of 10 x 8 negatives depicting scenery and life in India.

A framed portrait on opal of Mr. C. H. Talbot was next presented to the members by Mr. Friese Greene. The original negative was said to have been taken unawares by the electric light.

A vote of thanks having been passed, Mr. GREENE showed a sample of his new process for producing prints rapidly on an impermeable surface, and, in reply to a question, stated that the novelty consisted in preparing a suitable surface upon which chemicals would not act; all other details were the same as for bromide printing. He recommended, in printing without retouching, the interposition of talc.

Mr. ASHMAN (Hon. Secretary) then read his paper, entitled *The Emulsion Processes of Photography* [see page 376]. The delivery was accompanied by a series of experiments showing the method of compounding emulsions. Mr. Ashman also showed examples of various emulsion work on opal and paper, describing the qualities to be sought after. He also drew attention to the perfect manner in which small opals could be printed from any sized negative by means of Mr. Offord's frame.

A discussion followed, in which the Chairman, Messrs. Harbutt, Pitman, Friese Greene, and Walter Pitt took part.

The CHAIRMAN, in conveying the thanks of the meeting to Mr. Ashman, impressed upon experimenters the importance of noting all results at the time, and not by any chance to trust to memory alone, for years after making an experiment something might crop up by which the notes would be of great interest.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

MAY 30.—The President (Mr. W. A. Beer) in the chair.

Messrs. H. W. Guthrie and H. S. Nicklin were elected members.

The HON. SECRETARY read a letter from the Hon. Secretary of the Photographic Club (Mr. Edward Dunmore), recommending the adoption of the metric system. He also exhibited Talbot and Eamer's dark slide, and distributed

samples of Schözig's sensitised paper. He also acknowledged a gift to the library of six volumes from Mr. Beer, the President.

The PRESIDENT read a letter from the Secretary to the Royal Infirmary, acknowledging in grateful terms the gift by the Association of a large number of spare prints. He then referred to the resignation of the present Hon. Secretary (Mr. W. A. Watts), owing to business engagements, at which he expressed great regret.

Mr. HUGHES reported on the excursion to Rossett, which was fortunate both in numbers and weather; Mr. J. EARR reported on the one to New Brighton; and Mr. BEER reported on Bakewell and Haddon Hall, as to which he remarked, "That it was moist when we started, the noontide was moist, and it was moist at night."

Mr. Wilkinsons exhibited some prints by Blanchard's process, and Mr. ARCHER showed and explained a new American detective camera, the most important feature about which is its very moderate price.

Dr. G. A. KENYON then gave his paper and demonstration on *Film Photography*, in the course of which he remarked that there were three types of film—Eastman, Vergara, and celluloid. As regards the Eastman, the result left nothing to be desired, but the necessary work was somewhat laborious. The source of most failures in stripping he attributed to want of perfectly clean glass; he advised the use of Chance's patent plate, simply giving a thorough rinsing under the tap and leaving to dry spontaneously; he also advised the use of French chalk and the Eastman rubber solution. He exhibited stripping films in various stages and successfully stripped one which had been on the glass for two years. The ferrous oxalate developed films strip more easily than those developed with pyro, which tends to render the gelatine insoluble. The Vergara film he described as rather slow and requiring a special slide, otherwise no difficulty in working it. The Carbutt celluloid film was simply perfect; worked in all respects like a glass plate. The Fry celluloid he thought slower, but there was more difficulty with it than with Kingston plates.

All communications for the Hon. Secretary should be addressed in future to Mr. W. Hughes, 7, Crescent-chambers, N., 3, Lord-street, Liverpool.

BURNLEY PHOTOGRAPHIC SOCIETY.

MAY 29.—Dr. Brumwell (Vice-President) in the chair.

Mr. W. SUTCLIFFE gave a description of his visit to Scarborough last autumn. His first care was to be provided with a sufficiently strong camera to bear the strain of the equinoctial gales which occasionally endanger the stability of photographic apparatus. He gave a very humorous account of a mishap to his camera caused by a sudden gust of wind. Referring to the leading features of the scenery at Scarborough and the neighbourhood, Mr. Sutcliffe pointed out the various places where good photographic pictures may be taken. The paper was illustrated by a number of choice pictures taken under great difficulties. Some of the marine subjects were remarkably good. Several practical hints were also given in regard to the exposure and development of plates.

DERBY PHOTOGRAPHIC SOCIETY.

THE members of the above Society held their fortnightly outdoor meeting on Saturday last, when, by the kind permission of Mrs. Herriek, they visited Beaumanor. At Loughborough Station they were joined by the members of the Loughborough and Leicester Societies. The day was beautifully fine, and about one hundred and twenty-five plates were exposed on the Manor, old coach, and other objects of interest in the neighbourhood.

CINCINNATI CAMERA CLUB.

MAY 6.—Mr. George Bullock (President) in the chair.

One new member was elected.

A motion prevailed as to the sense of the Club that its interests would be best subserved by a declination of prizes of money value to members for work done on the annual excursion. A suggestion was adopted that the Excursion Committee offer diplomas for two or more grades of work done on the annual excursion, and that prints of the same be framed and hung in the Club rooms, with proper mention.

Mr. BULLOCK, after addressing the Committee on the work expected of them, read a paper on composition generally, and the duties of the Exhibition Committee specifically, especially with reference to lantern slides.

The reports of Treasurer and Librarian showed the Club to be in general good condition, forty-five new members received during the year, making a total to date of one hundred and thirteen.

MAY 20.—The President in the chair.

Two members were elected.

Mr. KELLEY read a paper following the papers of Messrs. Johnson and Bullock at previous meetings. Mr. Bullock had maintained that general interest in the picture should determine whether it should be publicly exhibited. Mr. Kelley, not ignoring the interesting, thought that selections should be governed by the technical and general excellence of the photograph as well. These papers provoked a good-natured and desirable discussion.

Dr. LE BOUTILLIER followed, advancing the merit of pictures with life in them, because they were apt to meet applause.

Mr. FISHER advanced novelty as a very desirable feature.

Mr. PECK beretically advanced the view that, as we cannot all be great artists, if the photograph is good and the maker and his friends are satisfied with it, it ought to be accepted.

Mr. JOHNSON, not disputing any one, thought that the exhibition each year should show study and improvement as to general excellence.

The CHAIRMAN of the Exhibition Committee gave assurance that each and all the ideas advanced would be considered in their selections.

The Chicago slides were shown at the close of the discussion, following which Mr. Prince gave practical demonstrations with positive films. Mr. Bullock also showed samples of his work with same.

PACIFIC COAST AMATEUR PHOTOGRAPHIC ASSOCIATION.

MAY 9.—President E. M. Runyon occupied the chair.

The Committee on the exhibition of *Illustrated Boston* made an interesting report. Over seven hundred people had filled the hall of the Association of Californian Pioneers, and as there were many Bostonians present, scenes familiar to them were greeted with applause.

The Committee on the preparation of the slides and the paper to illustrate and describe *Glimpses of California* reported some progress. The work had been completely mapped out, and so soon as gentlemen having certain negatives would send in slides and prints of them the collection would be completed, and the lecture ready for delivery. Negatives of those subjects not possessed by the Society were being made. In one instance a gentleman had volunteered to secure a negative of the San Diego Mission, the first settlement of the Spanish missionaries in California. This offer will be appreciated when it is understood that to do this means a trip of five hundred miles.

At the conclusion of the business of the evening, Dr. MAX BOELTE prefaced the exhibition of Dr. Piffard's new dark-room lamp by remarks upon the various experiments of Barton, Vogel, and others, towards securing a safe light for the dark room. Various negatives were exhibited which had been developed after long exposure to the flame of the lamp. They were without trace of fog, while other negatives exposed under similar circumstances to other dark-room lights were quite badly fogged. The construction of the lamp is very simple, consisting of a Bunsen burner, around the tube of which and projecting at the top is placed a cylinder of asbestos and sodium. The supply of air is regulated by a simple valve underneath, until the flame is seen to be entirely non-actinic or free from blue rays. To improve the lamp, and for further protection, an amber-coloured chimney is used. To those amateurs fortunate enough to have gas in their dark rooms this lamp will be a blessing. The Doctor also exhibited the Piffard flash lamp. It somewhat resembles an Argand burner in appearance. The principle is so simple that one wonders it has not suggested itself to every one making flash-light pictures. An air-pressure bulb is attached by a rubber tube to a cylinder. In this cylinder is placed a piston containing a lighted punk. Over it is a stand holding the magnesium powder spread on gun-cotton. A pressure on the bulb forces the lighted punk into contact with the cotton, and complete ignition of the powder results.

To conclude the evening, a number of interesting foreign slides, belonging to a private collection, were thrown on the screen.

Correspondence.

SUBSTITUTE FOR SOFT WATER.

To the Editor.

SIR,—In re "Foreign Notes," *et seq.*, 21th May issue. As a result of an experiment, I have been using water I prepared by dissolving one grain of commercial carbonate of potash to each ounce of pipe (hard) water from Kent Waterworks, letting it settle for three or four hours, and filtering it, after decanting it, through a plug of cotton wool pushed into the neck of a glass filter. If wanted in a hurry it can be filtered directly after a good shake up, but then first through a piece of sponge in place of the cotton wool, and after through the cotton wool. I take it the result of the adding the potassic carbonate to the hard water is partly mechanical (similar to Dr. Clark's process of softening water) and partly a chemical reaction, leaving an excess of K_2CO_3 . The water thus prepared takes the developer well. Testing it with soap, it lathers well. The nitrate of silver test for hard water when applied gives a thick deposit after standing twelve hours, and the water in the test tube, when a piece of plain paper is put in, gives no result by colouration. This test, however, is of no value, I take it, under these circumstances.

Now, as to the remark on p. 243, that "with hydroquinone ammonia appears unsuitable." Although I have not used ammonia for years, still I know the two first hydroquinone negatives I took in 1883 was with five grains hydroquinone, five minims ammonia 840, and five ounces water. The printing quality was all one could wish, the detail perfect, and the one of the two I have kept remains unaltered to this day. Of course this is not a keeping formula, for which I subsequently experimented, and which I have now obtained.—I am, yours, &c., W. T. F. M. LNOALL.

A NEW SHUTTER.

To the Editor.

SIR,—In offering your readers details of the mechanism of this shutter, I regret that without sectional drawings I cannot do so as fully as I could wish. It comprises all that Messrs. Reynolds & Co. claim for theirs, and embodies in it also the obturator of M. Guerry & Co., of Paris, with the addition of a disc on one side, to set the shutter to the proper inclination seen on the smaller shutters, with lines and pointer, thus giving the angle to the hook with clamping wheel attached, at which it is to be set on the notched trigger, so as to allow extra exposure to the foreground and a shorter one to the sky. The trigger holding the shutter captive, when the bulb is pressed sharply the flap is raised to a horizontal position and the shutter falls.

The novelty consists in being able to regulate the exposure, and so equalise and harmonise it (the exposure) to the foreground and sky. When the drop shutter is not in use it is still possible to use the trigger for regulating the exposure, or, by fixing the trigger down with the hook, to simply use the flap as such, with the obturator or stop-cock.

Thus there are three shutters in one, each with a perfect movement under the will of the operator.—I am, yours, &c., HARDING WARNER.

SHUTTER SUBJECTS.

To the Editor.

SIR,—I read the Benchers have kindly thrown open the Inner Temple Gardens to children, and that of the hundreds who pour in are many little ones from the narrow courts and alleys of the neighbourhood, who are minus coat, hat, shoes, or stockings.

Oh, London amateurs with quick plates and quick shutters, what an opportunity of subject is given you here! I envy you! Surely the opportunity will be greatly used, and surely the Benchers will have copies given to them.—I am, yours, &c., WILLIAM ADCOCK, Melton Mowbray.

THE EFFECT OF ELECTRICITY ON DRY PLATES.

To the Editor.

SIR,—In reference to the remarks in Mr. F. C. Beach's article (in your issue of May 24) respecting my experiments on electric action on dry plates, I may say that although daylight was almost perfectly excluded from the laboratory, a ruby lamp was alight during the experiments, but was usually turned with its dark side towards the plates while the electric discharges were taking place on them, and was sometimes placed behind a screen. I have been careful to avoid saying positively that I believed part of the effect was due to some cause other than the visible light of the spark, but I am inclined to think so. Consider the experiments where a discharge on the uncoated side of the plate produces by induction through the glass and the film peculiar and well-defined markings on the outside surface of the film opposite it; also those where the electrified foil was separated from the film by four thicknesses of gutta serena tissue, and yet left its mark on development. There may have been luminous action. But what is luminous action?

It was my difficulty in imagining what might be the immediate cause of the production of a latent image here that led to the remark, "Possibly further investigation may show that we have here a new kind of experimental evidence on the relation of electricity to light."—I am, yours, &c., Edenderry House, Belfast, June 3, 1889. J. BROWN.

THE TWO PHOTOGRAPHIC JUBILEE EXHIBITIONS IN BERLIN.

To the Editor.

SIR,—In the issue of May 31, p. 363, of your valuable JOURNAL, I read under "Foreign Notes" a communication respecting Berlin photographic societies and the intended Jubilee exhibitions here, which contains some errors you will allow me to rectify.

At first I may mention that I am not President of the German Photographic Society, whose centre is Weimar. In Berlin there are now three photographic societies—the Photographischer Verein (Photographic Union), the Society for the Advancement of Photography, and the German Society of Photographic Amateurs. I am President of both the last-mentioned societies. Exhibitions for this season are intended by the Photographic Union (President, Dr. Stolze), and the German Society of Photographic Amateurs. You will observe from that, that your contributor is wrong, if he says that the two societies have "similar objects and aspirations, and similar names."

Each of the societies has resolved, independently of the other, to make an exhibition this season, and whereas there does not exist an intimate connexion between the Society of Amateurs and the other Society (containing professional photographers, manufacturers, and stock dealers in general), and whereas the programme of the Photographic Union and the programme of the Society of Amateurs were quite different, the two societies have worked separately. Perhaps this appears still less surprising if I mention that in the past year, in Vienna, have been placed also two photographic exhibitions in the meantime—one of a more technical character, and another by the Society of Amateurs.

Even there is no *deus ex machina* here, who intends to unite the two societies or their exhibitions by high order. Minister Gossler had granted to the Society of Amateurs a room for the exhibition, but he was obliged to rescind this, because the annual art exhibition wanted the rooms. Minister Gossler made at first the condition to unite both exhibitions, if he would be requested to grant other rooms in his authority; but afterwards he declared to me personally that he had not known the very marked difference between both societies and their programmes.

In the meantime the minister of war has granted to the Amateur Society (which has a great many officers amongst its members), for its exhibition, the magnificent rooms of the Royal Académie of War, pretty near up the Linden, and the exhibition will be opened on the 19th of August—the birthday of photography.—I am, yours, &c., Berlin, May 2, 1889. DR. H. W. VOOGL.

A VERY convenient mode of mounting stereoscopic prints has been adopted by Mr. J. A. Forrest, of Liverpool. A neat morocco folding mount has inside, and at either side of the central fold, the two halves of the binocular picture. When opened out, it is ready for the stereoscope; when folded, it is an elegant case. This, if manufactured for the public, ought to take well.

Exchange Column.

- A couch-end posing chair for one of different pattern.—Address, H. HAWKINS, 60, Evelyn-street, Deptford, S.E.
 Will exchange 10x8 bellows camera and studio stand for whole-plate portable camera. Address, HANSEN, Gibson-street, Oakes, Huddersfield.
 Will exchange a half-plate burnisher and half-plate camera for a whole-plate burnisher.—Address, J. MEADOWCROFT, Photographer, Hilson-road, Nelson.
 Will exchange a five-inch double condenser in pe feet order for a half-plate portable camera and three double slides.—Address, CHARLES MANTELL, Thurning Rectory, Oundle.

Answers to Correspondents.

PHOTOGRAPHS REGISTERED:—

- J. Thomson, Liverpool.—One photograph of Cunard Royal Mail ss. "Unabria."
 F. M. Ratcliffe, Whitby.—One photograph entitled "Black and White."
 J. Paton, Greenock.—Photograph of Inman Line steamer "City of Paris."

- PRETSCHE.—See leading article in the present number.
 PHOTOFEL.—Wyleys & Co. Received. We are giving it a trial.
 FLORENCE.—We shall gladly welcome the views of which you speak.
 HAROLD R. HARTK.—On application to Mr. Harold Baker, Birmingham, you will doubtless obtain the necessary permission.
 INQUIRER.—Collotype is not a patented process, therefore you are free to work it to your heart's content, your friend's dictum notwithstanding.
 P. S.—You had better write to the City and Guilds of London Institute, London, S.W. You will then receive full particulars of how to proceed.
 R. H. ELDER.—You will not experience any trouble in photographing in Brittany. Special care must, however, be taken to abstain from photographing fortifications.
 JOHN COX.—Soak the negative in a solution of two grains of iodine to the ounce of alcohol until the stains become of a pale tint, then put the plate in the fixing bath for a few minutes.
 S. A. J.—We cannot tell you how Mr. Blanchard's paper "is prepared in the first instance," as that gentleman has not published the formula. He supplies the paper ready for use.
 MERICIA.—Large slabs of vulcanite can be obtained from the India-rubber, Gutta-percha, and Telegraph Works Company, Cannon-street, E.C. We believe they also supply a cement for the material.
 ASSISTANT.—Your late employer is not bound to give you a reference. If the facts are as you state, his withholding one is a great hardship to you, and certainly does not redound to his credit. Such petty spite is contemptible.
 W. W. W.—By all means employ a bi-lens camera for stereoscopic portraits. A shifting front will enable you to get the same stereoscopic effect, but the convenience of securing the two pictures simultaneously cannot well be over-estimated.
 AJAX.—1. It is quite a matter of taste; most professional photographers, however, prefer wood.—2. Secure the cards tightly in a vice or screw press and take off the corners with a plane, then finish with a scraper. Some little practice will be necessary to do the work neatly.
 CRANUS writes: "Will you kindly give the formula for paint used for working up carbon and other prints in black and white that will not change colour?"—Ordinary water colours blended to match the tint of the picture, whatever that may be, avoiding the use of lakes, which are all more or less fugitive.
 S. CRAIG.—You would have no difficulty in obtaining a patent for the apparatus, but you would have great difficulty in maintaining it in a court of law. The same or very similar contrivances have been in use for the last thirty years, and, if we are not mistaken, have formed the subject of more than one patent.
 M. DAVIES.—If you wish to make good lantern slides you should avoid the use of extra rapid plates, as they are not at all adapted to the purpose. Very slow plates, as a rule, are much better. Why do you not employ the plates that are specially prepared for lantern transparencies? They yield the best result of all.
 W. J.—If the ink comes off the mounts when the prints are rolled or burnished it is clear that it is faulty, and you have a good cause of complaint against the one who supplied the cards. However, the ink will probably dry with time. Spread the mounts out and leave them exposed to the air in a warm room for a few days.
 BORE.—It is impossible to say the cause of the spots on the print sent from a casual examination. They may proceed from something in the manipulation, say, particles of floating matter settling on the picture while it is wet, and so inducing an incipient fading, or from something in the mountant used, or possibly from the mount itself.
 R. BILLINGWOOD.—The old-fashioned single landscape lens was, as you say, an unwieldy instrument and gave distorted lines, and you may "wonder they ever used such a thing." But you will perhaps be surprised to learn that no better lens is yet in existence for pure landscape photography. Many of our best artists take all their landscapes with single lenses. Your sneers at single lenses are a little out of place, as you will find when you have gained more experience.
 CANTAR.—The cold is produced by the act of dissolving the nitrate of ammonia. If the vessel in which solution takes place be kept carefully covered by a jacket of non-conducting material, such as a few thicknesses of felt, then will the liquid be kept in a cold condition for a considerable period. When its temperature rises to that of the atmosphere its virtue is gone, only to be reascited by recrystallising the salt and redissolving it. The proportions suitable for producing the best effect are stated to be equal parts of water and nitrate of ammonia. The water should be the coldest that can be easily procured.

B. A. ROME asks who are the proper parties to apply to for permission to take photographs at the Crystal Palace.—Messrs. Negretti & Zambra have the sole right to photograph in the Palace and grounds, and they, we believe, will not grant permission to any one. However, you might write to them, they are the only ones who can grant you permission.

J. B. KEEN complains that all the negatives he takes with one of his lenses are thin and without detail at the corners, although it was sold for the size plate for which it is used. It is, he says, a portrait lens without a name.—The fault is, no doubt, with the lens. Many portrait lenses will not cover the size plate they are said to do. Better get a lens of longer focus.

COLESWORTH.—If you have been making your own varnish successfully for six or eight years you ought to meet with no difficulty in continuing to do so. Possibly you have obtained some indifferent resins. We should advise you to get some fresh from a different source. Unbleached shellac simply dissolved in spirit, without further treatment, makes a very good varnish for negatives. Possibly it is your clarifying treatment that has caused the brittleness.

W. A. MEIGH writes: "In your JOURNAL, a week or two back, it was recommended to try plates 'backed' for landscape work. The other day I made the experiment with half a dozen plates, and got far better results in each case than I should have done had I not had the plates backed; I get a denser and sharper negative without it taking any longer to print. I should very much like to hear what others have to say with regard to 'backing' plates for landscape work."

LOCOMOTIVE says he has been taking photographs of some engines for an engineer, who has returned the proofs, saying they were of no use, as they were not like the pictures shown by several other firms who use photography in their business. He admits that his work is certainly not so good, and sends us a print of his own and one which his customer has sent him, and asks how he can produce work like it.—Our correspondent has taken his photograph from the bare metal work, whereas the other has been taken after the engine was prepared specially for being photographed. Engineers who employ photography regularly paint the metal over with a flat colour of a slate tint to dull the bright metal. This fully accounts for the difference in the two results.

W. MCLEAN writes: "I shall feel obliged if you can give me a remedy for the following:—For the last three weeks I have been troubled with tears on the albumenised paper in sensitising; either the paper is repellent or the bath has by some means got into such a state that it will only adhere in beads, and not distribute itself equally and drain as usual. I have tried kaolin and permanganate of potash; I have also weakened and strengthened by adding more water, then more silver, to no purpose. If you can assist me out of the difficulty I shall feel obliged."—Sometimes the addition of a little alcohol to the sensitising bath will overcome the difficulty, but the best remedy is to keep the paper for some time in a damp place before floating it. Should both these remedies fail the paper must be blotted off before the tears form. This may possibly necessitate a longer floating or the use of a stronger silver bath, but there is no help for it unless the paper be discarded.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting, June 12, 1889, will be *Rapid and Slow Gelatine Plates*. Bank Holiday outing at Aylesford, Kent. Trains from Cannon-street, leaving by train nearest ten o'clock. It is suggested members should inquire on Saturday as to Bank Holiday arrangements.

DEODORISED ALBUMEN PAPER.—Few are unacquainted with the offensive smell which characterises much otherwise excellent albumenised paper of foreign preparation. We are pleased to learn that Messrs. Thos. Thorns & Co. have discovered that this smell may be quite eliminated without interfering in any way with the good quality of the albumen surface. This Mr. Thorns effects by a special method of treatment with animal charcoal, which, however, is not brought into such contact with the surface as to damage it. He has made application for a patent "For Extracting from Albumenised and Sensitised Bright Surface Paper all Unpleasant and Obnoxious Smells." A sample of the paper which has been submitted to us attests the accomplishment of this desideratum.

HOLBORN CAMERA CLUB.—The following are the arrangements for June, at all of which visitors will be welcome:—Friday, June 7, Mr. E. Clifton will give a demonstration in the Club Room at eight p.m., when he will make some dry plates, and explain their chemical composition and the action of light and developer upon them. Friday, June 14th, Mr. G. A. Freeman, B.Sc., F.G.S., will lecture on the *Chemistry of Photography*, at eight p.m. Saturday, June 15, Field-day to Windsor. Friday, June 21, Mr. F. Brocas's demonstration on *Toning*, at eight p.m. Saturday, June 29, Field-day to Burnham Beeches. The full arrangements for the field-days will be posted up in the Club Room a week in advance, and in the event of rain or totally unsuitable weather for photography, the outing will be carried out on the Saturdays following the above dates. Mr. Fred. Brocas, Hon. Secretary, 100, High Holborn, W.C.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1519. VOL. XXXVI.—JUNE 14, 1889.

DEFECTS IN SIDEREAL PHOTOGRAPHS.

IN a letter from the Astronomer of the Imperial Observatory, Rio Janeiro, published on another page, that gentleman directs attention to an hypothesis we gave at the Camera Club (on the occasion of a lecture by Mr. A. A. Common, F.R.S.) relative to the seeming anomaly of stars, which when seen by the most powerful telescopes are only points, yet in a photograph become expanded into discs of greater or less dimensions, according to their luminousness.

This hypothesis was also dwelt upon with somewhat more minuteness in an editorial article in this JOURNAL for December 21, 1888. We there mentioned what we believe is the true cause, primarily, of the photographs of some stars being larger than others, although the images in themselves are but points, and explained it to be due to a lateral radiation of light from one particle of silver bromide to another, which extends all round, and to a distance, from the luminous point, in strict relation to the brilliance of that point. This was the species of halation to which we attributed the conversion of the star points into discs, although we recognised the existence of that other halation, caused by reflection from the back of the sensitive glass plate on which the telescopic images are received.

It is this latter to which our correspondent, Professor Morize, is inclined to attribute the phenomenon in question, and there is no doubt that it may exert an influence in addition to the radiation spoken of. One reason for our thinking so arises from the following:—When Sir Howard Grubb at the Society of Arts projected some star images on the screen by means of the lantern, we noticed that many of the larger stars towards the margin of the screen were very slightly oval in form, those at the centre being circular. We observed the same thing in some others, including some lately shown at the Photographic Society of Great Britain.

The obliquity of the incidence of the star images towards the margin of a quarter-plate would be too slight, when formed by an object glass of long focus, to give countenance to the possibility of this proving the cause, even if the images were projected with a visible disc, which we know is not the case. Then, whence arises this oval form?

It can only arise from halation or reflection from the back of the plate, as pointed out by Professor Morize, and illustrated in the diagram which accompanies his letter. The determination of this cause suggested by him, viz., to silver the back of the plate and thus intensify the action, seems excellent, and if tried would throw such light upon the matter as would place its possibility beyond the realm of conjecture or hypothesis. On the other hand, the backing of the plate with a dark-

coloured, light-absorbing material in optical contact with it, such as photographers employ when taking a dark interior in which there is a bright window, would provide the means by which such halation would be overcome.

As hinted by our correspondent, this elongation of the star discs, by displacing the position of their true centres, introduces an element of disturbance, although a slight one only, in determining accurately the relation of one star to another, and it is well to have every source of error eliminated.

HYPO SOLUTIONS.

IN continuing our remarks upon the stability or otherwise of solutions of "hypo," it will be thought by some that they may merely be of academic interest, seeing that it is the custom to use fresh hypo for each day's work. Such is, however, not really the case; many professionals use their fixing solution—for negatives, at any rate—for many days without changing, while amongst amateurs we are afraid to say too common we believe the custom to be of saving their print-fixing solutions for use on subsequent occasions. Then, again, in establishments where it is the custom to make "saturated solutions" of various chemicals, the hypo solution stands a chance of being kept a considerable time. The salt we are at present considering is a conspicuous example of the varieties that these so-called saturated solutions may exist under. If a glass flask be half filled with hypo crystals without any addition of water, and heat be applied, the whole mass will become perfectly liquid. If next a plug of cotton wool be put in the neck, and the flask be allowed to cool, the solution will remain liquid for an indefinite time, even when repeatedly shaken, if the plug be not wetted. We should like to know in what light this solution would be regarded by the "saturated-solution" advocates. Finally, with regard to this liquid, if the plug be removed and a minute crystal of hypo be dropped into the liquid, the whole will almost instantly become a solid mass, and at the same time become so hot that the flask can scarcely be held with comfort. Then, again, if a solution of hypo be made with water in the ordinary manner, so as to contain as much of the salt as possible, it will be found that if a single, well-formed crystal be placed in it, and allowed to stand without stirring the liquid, it will daily grow in size, evidently from abstraction of the salt from the solution, thus showing that the presence of crystals of a certain salt in a solution of that salt will tend to lower its strength, and that a saturated solution will not be obtained. Indeed, we may say that to obtain a really saturated solution is a matter of no mean

difficulty. We cannot therefore do better than advise, at any rate with regard to "hypo," that saturated solutions be displaced by solutions of known and definite strength. But, as we have said, thiosulphate of soda is useful, not only for photographic purposes under its well-known name "hypo," but also for the purposes of the professional chemist, and several methods have been devised for preserving it with its qualities unimpaired.

The tendency to decompose is shown most decidedly in the light; hence it is desirable always to keep the solution in a dark place, this, again, being contrary to the practice of some photographers, who leave a bottle of fixing solution in strong daylight, or, on a large scale, their vat or other vessel of saturated solution unprotected from the light. Any one may easily prove this want of stability himself. Let some solution of hypo be placed in a clear glass and settle in daylight, and it will be seen that after a while, even in the dark, but more especially in the light, a decided deposit will take place on the sides of the bottle, and examination shows it to be sulphur. Here at once is a suggestion for one cause of fading; if hypo solution is changed in composition so as to deposit sulphur, we may be quite certain that if prints are put in that solution to fix there is a probability of sulphur being deposited upon or within them, an effect the evil of which is too well known to be looked on with equanimity.

Years ago Mr. Spiller showed the advisability of using carbonate of ammonia in the print-fixing solution, with the intention of removing the whole of the unused silver salt, so as to insure against future change or fading; the whites themselves he found to contain a silver compound not wholly soluble in hypo, but which was removeable by the carbonate of ammonia. It is singular that this should be so, for one of the leading continental authorities on the system of analytical testing by solutions of definite strength says that the change in hypo solutions just described can be entirely arrested by adding this same sesquicarbonate of ammonia, in quantity about eight per cent. of the weight of the hypo employed.

In the *Philosophical Transactions* the same subject has been referred to, Messrs. Harcourt and Esson both recommending caustic soda for the same purpose.

Quite lately the subject has been again referred to, and a short abstract appeared in the *Chemical Society's Journal* of a paper by H. Bornträger, which writer recommends salicylic acid. He states that a small pinch to a pint of "hypo" solution will greatly retard the tendency to decomposition.

We should be inclined to deprecate the employment of any acid in solution of hypo intended for photographic purposes, lest the very evil intended to be averted should be brought about; that is to say, the upsetting the equilibrium of the solution in such a manner that unstable silver compounds might be in danger of being produced within the texture of the film or paper, and so lead to future alteration.

We think it very desirable to bring before our readers a point that is now so rarely heard of—the value of ammonia carbonate in fixing solutions; and it was this fact that suggested to us that some remarks upon the stability of solutions of hypo would be both useful and appreciated, and once again draw attention to a valuable recommendation.

In conclusion, we may say that we have used large quantities of carbonate of ammonia (the ordinary "rock ammonia," purchasable at the chemists' shops) for fixing prints, and, provided that it was not used in a larger quantity than we indicate, we have not found the slightest harm to occur from

its use, while there is the added great satisfaction of feeling that the prints made by its aid are protected from fading possibilities to the utmost extent possible.

A GRACEFUL acknowledgment of what is owing by the public to Dr. R. L. Maddox comes from the Franklin Institute, Philadelphia, as will be seen from the following announcement in its *Journal*:—"Notice is hereby given that the Committee on Science and the Arts of the Franklin Institute has recommended the award of the John Scott legacy medal and premium to Dr. Richard Leach Maddox, of Southampton, England, for the 'Substitution of Gelatine for Collodion in Photography.'" We congratulate the Franklin Institute upon having taken this step to recognise so publicly the services of a most worthy gentleman, and we also tender Dr. Maddox our congratulations upon his merits having received such acknowledgment.

THE rumoured combination amongst dry-plate makers, to which we referred a short time back, to raise the price of plates to a considerable extent, has, we learn, fallen through. Some of the larger makers, we are given to understand, refused to join the ring, their reason being that any material rise in the price would at once open the market to foreign competition. They were doubtless right in their surmise. At the present prices there is very little to induce foreign makers to send their plates to England. But, with even a much smaller increase in the price than was mooted, the case would be widely different. The fact should be borne in mind that a considerable quantity of the material used by English plate makers is imported from abroad. Labour also, as a rule, is cheaper on the Continent than it is in this country.

WE have an example of foreign competition in the albumenised paper trade. A very large proportion of the albumenised paper—both "ready sensitised" and insensitive—used in this country is prepared on the Continent. This is scarcely to be wondered at when we consider that the English maker has to draw his supplies of the raw material from abroad. The paper itself is made on the Continent, as British paper makers cannot, or at least do not, make a suitable article. Foreign eggs have to be used, as English ones, for the greater part of the year, are far too expensive for the purpose. Now freight is little, if any, more on the prepared paper than it is on the unprepared; whereas the carriage on the eggs is an important item in their cost. Hence it will be seen that, with the higher cost of labour here, the home manufacturer is placed at an immense disadvantage. Those dry-plate makers who held aloof from the proposed combination were, we think, wise in their generation. While the prices remain as they are, there is little to fear from foreign competition in this direction.

THE project of the Photographic Club to introduce the metric system and make it universal in photography appears to be meeting with every success. Measures graduated with cubic centimetres on one side, and ounces, drachms, or minims, as the case may be, on the other, are now to be had commercially. These will greatly facilitate the introduction of the system, as any one can, without calculation, see at a glance what in one system is the equivalent in the other. This idea might also be carried out with the weights. The gramme weights might be stamped with their equivalent in English grains. To be strictly accurate, this, it is true, would involve going into fractions; but for all weights, say over the gramme, the nearest whole number would, practically, be correct enough for all photographic requirements. For less than the gramme, the half or the quarter of a grain will be near enough for all purposes.

NEVER, perhaps, has photography figured so largely on a race course as it did last week at Epsom. Possibly there were fewer large cameras present than on some former occasions; but they were more than compensated for by those of the detective class. However well a detective camera may be disguised, it seldom fails of recognition by

those familiar with the art. These cameras, from the miniature "Kodak" to the more pretentious half-plate size, were to be seen by the score.

MANY attempts have for several years past been made to obtain an instantaneous photograph, on a moderately large scale, of the "Derby," but up to the present we have not seen even a moderately good result. Successful and very characteristic groups and scenes on the course, secured by "instantaneous shots" of the detective size, have been common enough; but a large instantaneous photograph, taken direct, of really good quality, has not yet come under our notice, notwithstanding all the attempts that have been made. Why this should be the case it is difficult to say, seeing that excellent instantaneous views of London, even in the heart of the city, are to be seen almost everywhere, and the light in London is certainly not better than that at Epsom, particularly during the race season. However, it may be that London street scenes are with us all the year round, and a failure one day may be followed by a success a few days afterwards. But the Derby is but an annual event, and a failure, from whatever cause, means waiting a year for the next opportunity.

ON more than one previous occasion we have advocated the employment of photography in deciding races, though, so far, it has not been adopted in this country. However, according to a recent number of our French contemporary, *La Nature*, it has been carried out on some of the race courses in Germany, and as follows. At a few metres of the winning point several cameras are arranged at short distances apart, and as the horses pass the exposures are made by electricity. By this means an incontestable record of the result is secured.

BACKING plates, notwithstanding the advantages accruing therefrom, is usually voted a bore by most people. The usual method of applying the colour is by means of a brush or a piece of sponge, but, with either method, the operation, it must be confessed, is a somewhat messing one. At a recent meeting of the Photographic Club Mr. Carter showed a very neat and simple method of applying the colour with a roller. The roller is a composition one, like a printer's ink roller, which in fact it is in miniature—such as are supplied with some forms of letter-copying apparatus. This roller is charged with the colour and then simply passed over the back of the plate.

INDIARUBBER rollers, which will answer for the above purpose, are now to be had at most photographic stores, where they are sold for mounting purposes. A suitable material for the backing is a non-actinic pigment, such, for example, as burnt sienna mixed with water and a little dextrine to a thickish cream-like consistence. A small quantity of this mixture is distributed, fairly evenly, with the roller on a glass plate, after the manner that a printer works up his ink roller, then the roller is passed once or twice over the back of the plate, when a perfectly even coating is obtained. By this simple method two or three dozen plates may, without soiling the fingers, be backed in a few minutes. If methylated spirit be made to take the place of a large proportion of the water in the mixture, the coating will dry in a much shorter time than if water alone were used.

A few years ago some very fine large portraits, by Bergamasco, of Russia, were exhibited in this country, and they attracted a good deal of attention at the time. The pictures were vignettied, head and bust, of large size—about five-inch heads. The special feature about these pictures was that instead of being vignettied into a white background, as usual, they were vignettied into a black or very dark one, which rendered the face remarkably brilliant. Some few photographers essayed the same style, though on a far smaller scale—mostly of the carte and cabinet size—but these met with little commercial success. Now that the demand has arisen for large direct pictures, those who are in search of novelties in portraiture might give this particular style consideration.

THE FORTHCOMING EXHIBITION OF THE PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

It has now been decided that the Annual Exhibition of this Society will open by a *conversazione* on Saturday, September 28, and will close on Wednesday, November 13.

Medals will be placed at the disposal of the judges for artistic, scientific, and technical excellence, and for transparencies and apparatus.

The judges elected by the Society are Messrs. W. Bedford, V. Blanchard, Geo. Davison, W. England, J. Gale, Henry P. Robinson, and J. Traill Taylor.

Further particulars will be duly announced.

THE WHOLE ART OF PHOTOGRAPHY IN A SERIES OF EASY PROGRESSIVE LESSONS.

CHAP. V.—FERROUS OXALATE AND HYDROQUINONE DEVELOPERS.

A FEW words more concerning the ferrous oxalate developer ere it is dismissed for the present.

After its components are mixed, this developer will not keep for any length of time if exposed to the atmosphere. And yet, by adopting the following expedient, it is not only enabled to keep for a considerable time, but also to be used with a great degree of comfort. Provide a bottle of any desired capacity, from a pint to a gallon, having an aperture near the bottom—say an inch from it—by which any required portion can be drawn off as it is wanted; and after it has been nearly filled with the developer, pour into it as much paraffin oil or kerosine as will form a stratum from a quarter to half an inch in thickness on the top of the developer. A small funnel is inserted in the mouth instead of the cork.

Some dealers keep bottles of this class in which a little spout is melted on to the bottle. On this spout is sprung a piece of rubber tube, at the other end of which is a spring clip, by which it is pinched. The bottle, thus prepared, is placed on a shelf a little above the table or sink on which stands the developing tray; and by releasing the pressure upon the clip, any desired portion of the liquid may be drawn off and, when done with, returned to the bottle through the funnel at the top. When the developer loses its energy by age and use it may be usefully employed in conjunction with some that has been freshly made. It is no secret that an old ferrous oxalate developer imparts a much more pleasing tone, especially to a bromide print, than one which is quite new.

A modification of the method described for preventing the oxidation of this developer, due to Mr. Cosmo I. Burton, consists in keeping it in a flexible indiarubber bottle or ball of any suitable size and form, having attached to it, as in the previous case, a piece of tubing closed by a spring clip. This, when filled, is laid upon a shelf a little above the level of the sink where the development is to be carried on. The used solution cannot be returned to the reservoir, but that which remains will keep good.

In either of the two systems described the services of the spring clip mentioned may be dispensed with by raising up the lower end of the rubber tube to a higher level than that of the reservoir.

The hydroquinone developer has acquired a deserved degree of popularity, and many who had bestowed their affections upon iron and pyro have deflected them towards the new favourite. For a long time has it struggled for recognition through good and evil report, but that recognition is now attained.

So many formulæ for compounding this developer have been published that we are slightly at a loss which to select for the beginner. But one cannot go far wrong in giving that recommended by Mr. J. W. Swan in a communication to the Photographic Society of Great Britain, the result of many experiments carefully conducted.

A.	
Hydroquinone	80 grains.
Citric acid	10 "
Sulphite of soda (recrystallised)	80 "
Distilled water	20 ounces.

B.	
Caustic potash (fused)	160 grains.
Sulphite of soda	160 "
Distilled water	20 ounces.

C.	
Bromide of potassium	24 grains.
Distilled water	1 ounce.

D.	
Caustic potash	160 grains.
Distilled water	20 ounces.

For normal exposures use equal parts of A and B, adding five minims of C for every ounce of solution.

For over-exposed plates, use D instead of B, with an extra quantity of C.

For under-exposed plates, omit C, and in extreme cases add six or eight grains more of sulphite of soda to each ounce of the developer. The object of increasing or decreasing the quantity of sulphite is to give greater or less density.

As we have said, the formulæ which have been recommended by various successful workers for mixing the hydroquinous developer are very numerous, and various alkalies other than the caustic potash in the foregoing have been employed, among these being meta-bisulphite of potash, carbonate of potash, carbonate of soda, carbonate of ammonia, &c. But we advise the reader to adhere to the one given until all its peculiarities have been mastered and familiarity with its working acquired, after which he may make trial of others, ultimately adhering to that which he finds the best for use with any particular brand of plates he prefers.

This developer answers equally well for negatives, for lantern and stereoscopic transparencies, and for bromide paper prints.

THE THEORY OF THE STEREOSCOPE.

IN the series of articles on *Stereoscopic Photography*, which I recently published in the pages of this JOURNAL, and which series commenced in January, 1888, and terminated in August last, I confined myself almost entirely to those practical details with which twenty years of industrious experience have made me perfectly familiar. The whole of my theoretical observations put together would, I fancy, scarcely fill a column—certainly not a page; it is, however, very desirable that something should be said by somebody on the theory of the stereoscope, not only for the advantage of the rising generation of photographers, amateur and professional, who know nothing of it, but for the advantage of those older hands who know a deal of what is wrong.

I have already pointed out with emphasis, and repeatedly, that one of the great causes for the decline of stereography was to be found in the incorrect manner of making the negatives, another in the incorrect mode of printing from them, and a third in the incorrect manner of mounting the prints when got. There is, however, still another cause for the decline of stereography, and that is the total ignorance which did prevail, and the partial ignorance which does prevail (and prevails extensively), of the true theory of binocular vision and of the stereoscope.

It is a bold and an astonishing thing to say, but nevertheless a true one, that for this ignorance we are chiefly indebted to the two men by whom the two forms of stereoscopes were invented—to Sir Charles Wheatstone, the inventor of the reflecting stereoscope, and to Sir David Brewster, the inventor of the refracting or lenticular instrument. Both these gentlemen were thoroughly imbued with the idea—of which they were seemingly incapable of getting rid—that stereograms, when properly seen, were viewed with a *convergence* of the axes of the eyes.

In the pages of this JOURNAL in 1873 the late Mr. Thomas Sutton vigorously and gallantly combated this idea, but so far as the two eminent opticians, who were his opponents of the time, were concerned, he seemed to have combated it in vain. Nevertheless, that Sutton was right and his opponents wrong is as demonstrable as any proposition in geometry, as was evident to Sir George Biddle Airy (the Astronomer Royal of the period), and to Professor Piazzini

Smyth (The Astronomer Royal for Scotland), and to other eminent mathematicians of the time.

I am no mathematician myself, and don't pretend to be, but I am able to demonstrate by experiment that Wheatstone and Brewster were both wrong in the matter of converging axes, and that Sutton was quite right. I am able to offer some common sense argument against the idea that everything to be seen right must be "squinted" at; and I think I am able to produce the one argument which Sutton did not use, by showing how probably Wheatstone and Brewster became afflicted with the mania for converging axes.

If we look at a card with markings on it at a distance of twelve or eight inches from the eyes (as the case may be), in order that we may see it as *one* and not as *two*, it is necessary that the optical axes of the eyes shall be converged, so say the supporters of the converging axes theory, and they say so truly *if we are to look at it with the unaided eyes*.

But when we look at a binary picture in the stereoscope, whether the instrument be a reflector or a refractor, whether it be Wheatstonian or Brewsterian, we look at it through an apparatus which is lenticular; in fact, in both appliances "magnifying glasses" are employed and the conditions are entirely changed.

Besides, it should always be remembered that what we *seek* to look at is not a piece of card with markings on it so many inches off, but an illusion in the air, at the solid phantoms of solid things, subtending the same angular magnitude as the originals, producing the same or very similar effects upon the retina, and colour, and knowledge of what the "slides" in reality are apart, capable of being mistaken for the originals themselves.

The rays which reach us from distant objects, such, for instance, as the point of a church spire on the horizon's verge, strike the eyes in what would be called "parallel" rays by anybody who was not over anxious to be pedantically correct. The convergence of lines drawn from a base of about two inches and a half (the distance between the eyes) to a point some miles away is certainly too trivial altogether to be taken into account in the practical affairs of life, and in order to get the illusion of reality which we seek by stereoscopic aid, objects so distant as to present practically parallel beams in nature must be seen in their representations by practically parallel beams in the stereoscope. If they are not, they won't seem as far off as they should, and everything will be (optically) reduced, so that a "slide" representing, say, a town, as seen from a position of eminence, will present—not the aspect of the town—but the aspect of a little model of it; and this is the kind of aspect which everything presents as seen in the Wheatstonian and Brewsterian stereoscopes with their converging axes of the eye.

"Every one" who is in the habit of practising stereographic photography is able easily enough to "squint" a "slide" into the negative solidity of the pseudoscope. It is quite as easy, however (after a little experimenting in a proper way), to combine it so as to produce the positive solidity of the stereoscope, and it is more desirable to do this; but whichever method is adopted, the process is tiring to the eyes—and why? Because the process is "unnatural," and requires an effort, of which we are conscious, to perform it. And why an effort? Because, in the ordinary practice of binocular vision for the purposes or pleasure of our daily lives, when we "focus" the image of an object at a given distance on the retina, we also converge the optic axes through a certain arc. But when we "squint" or converge the dual pictures of the stereogram into the appearance of relief, we converge the optic axes in the one case more, and in the other case less, than they are converged for the same focal distance of the retina in ordinary vision.

When lenses are looked through, however, the case is altogether different. Our power of focussing on the retina is practically at an end. It is no longer by a movement of the mechanism of the eye that the images are made sharp; it is either by the movement of the things or a bodily movement of ourselves that we bring them into "focus" now. (It is, of course, in relation to convex lenses only that I speak.)

The optic axes now are parallel or converged by the nature of the pictures we inspect. If these contain "objects" substantially alike, and separated from each other by the distance between the eyes, we see them by parallel vision without the consciousness of effort. If

they are separated (in reason, of course) by an interval which is less than the optic axes converge "of their own account," the focussing operation of the eye (now of no avail, for good or ill) is, as usual, automatically performed from habit, and the object advances into optical relief.

The components of a stereogram should always be mounted with the distant objects separated to the distance of the centre of the eyes, as used for parallel vision. They should always be viewed through lenses which are entire, and not through magnifying prisms. Those lenses should be of the same focal length as the lenses with which the negatives were made, and these lenses themselves are the best which can be had. Their centres should be separated by an interval equal to the distance between the eyes, and (as would be the case in these circumstances) their centres, and not their edges, should be used. Now comes the question, How came Wheatstone and Brewster by the converging craze?

There is no absolute evidence on the point, but the probability, seemingly, is this: they tried their inventions without the magnifying lenses before they tried them with. What more likely thing than this? If so, the images had to be focussed for their actual distance, to make them sharp, by the mechanism of the eyes, mechanism habituated to the working with given degrees of axial convergence for each varying focal length. These degrees of convergence, doubtless, both Wheatstone and Brewster ascertained for the distances employed, and did so before the magnifying lenses were applied, and hence, having definitely ascertained that, in the circumstances of their experiments, combination was most easily effected by the optic axes which converged, they overlooked the fact that the lenses remove the function of focussing from the eye, and so continued the employment of the converging axes when their use was gone, and in consequence of which evil alone ensued.

I have a Brewsterian stereoscope by me as I write. It is a genuine "old stager," having been purchased by my father at the time of the London Exhibition of '51. Examining the "slide" either of that period or of this with it becomes a painful occupation for the eyes.

When, however, a "slide" is divided, and its dual pictures separated by a space of an inch and a quarter in length—an operation which makes parallel the emerging rays—the relief is perceived with ease. I have just performed the experiments as I write.

Stereography is most certainly coming in again. Let every photographer who has sense enough to adopt it see to it that his "slides" are properly made, and let him offer for inspection or for sale himself instruments in which they can be properly seen.

W. I. CHADWICK.

ECHOES.

I was greatly interested in the editorial account of the latest freezing method, which I had only a dim notion of from previous hearsay. But that is only available for practical dry-plate purposes on a large scale, while there are many occasions in even the smallest laboratory when a cheap and ready cold producer would be a boon. The nitrate of ammonia method is simple and inexpensive, but, unfortunately, unless it be kept for the special purpose—and that, too, in quantity—it is not available just when wanted.

But our old friend and enemy, "hypo," I venture to think, is usually to be found in any dry-plate worker's establishment, or if not, it ought to be, in sufficient quantity to produce a moderate cooling effect at very short notice. Scarcely any photographer of the present day needs to be told that though not equal to the nitrate in that respect, hyposulphite of soda in the course of solution "produces" a pretty intense degree of cold, quite sufficient for most cooling purposes, as the solution itself descends below the freezing-point. But, truly, it is not a nice thing to have about the dark room in a promiscuous way unless great care be exercised to see that it keeps itself in its proper place.

Fripping—a fault much less frequently met with nowadays than a few years ago—is not caused merely by high temperature, though as a matter of course that is a powerful incentive. Irregularity of temperature is a far stronger temptation, and a gelatine film that will successfully pass through the ordeal of development in nearly warm solutions, if fixed and washed at the same temperature, will

often give in if the intermediate washings are performed with much cold water. It is much the same with human tempers; they may remain placid enough under any amount of one kind of worry, but a multiplicity of troubles will break down the sweetest disposition. This, however, is only a digression.

Now it strikes me as a very simple, and I know from actual use it is an effective plan to adopt in the very hot weather, at least if you are not working on a mammoth scale, to relinquish the use of water direct from the tap or ordinary supply, but to establish a temporary cistern in the form of a jar or jug of moderate capacity, say holding from half a gallon to a gallon and a half, and to place this in a basin or other convenient receptacle packed round with crystals of hypo, kept moist with water far from sufficient to dissolve them. The temperature will be lowered until the water has dissolved as much hypo as it will, when the addition of a little more will re-establish the refrigerating process. When the crystals are all dissolved, the saturated solution can be bottled off for fixing purposes.

That brings me to another leader, in the same number of the JOURNAL, on *Hypo and Hypo Solutions*, in which the dictum of "Watts," on the question of the stability of hypo in solution and otherwise, is queried. I can only say that I have myself long had doubts as to the correctness of the statement quoted in the leading article referred to. I have for years made a practice of keeping a stock of hypo in solution ready for use, and at times this has been many months old before it has been actually used, yet I never noticed any difference in its behaviour. Some years ago, through the liberality of a friend who was retiring from photography, I became the possessor of the best part of a one hundredweight cask of hypo—a quantity sufficient, at my then rate of working, to last the rest of my natural life. At any rate it did last some years, and though it *deliquesced* a good deal, and left a mark whereon it stood for long, I never saw any sign of *efflorescence*, nor did the last of it prove inferior in fixing power to the first.

I did not see the article referred to by Mr. W. I. Chadwick on the *Influence of the Stereoscope*, but I can fully join him in his protest against such nonsense as attempting to condemn the instrument because some lunatic expresses an erroneous idea of its capabilities and uses. I fail to see why "F. M. S." or any other artist should depreciate the instrument, unless it be from motives of envy or jealousy, because it renders a degree of solidity and reality that his poor powers are helpless to emulate. I don't quite see, either, why a photograph, if artistic in its single form, cannot under the necessary conditions be duplicated so as to give in the stereoscope an equally artistic and at the same time true representation of the subject. But it seems to be the practice, if not the prerogative, of "artistic" minds to gird at anything of a "mechanical" or "scientific" nature. Why, then, does not "F. M. S." relinquish the camera?

Some short time back I quoted from a speech of an old photographic friend to the effect that people who preach on the subject of photographic art do not always shine in their efforts. A man may be a good artist because it is in him, but a bad teacher, and therefore he cannot give out to others the artistic sense that he himself possesses. The art was born in him, and he found art easy; the teaching capacity was not born with him, but he expects to find it come to him with equal facility, and without the trouble of learning. Consequently, when such a man commences to try and teach his own particular subject, he generally ends as he begins—by making a glorious mess of it.

From art back again to more congenial topics! I notice that Mr. Cowan has succeeded in tracing the cause of the staining that sometimes occurs with hydroquinone to the employment of a particular bromide—bromide of ammonium—as the restrainer. This, in the hands of a careful experimentalist like Mr. Cowan, would seem to point to ammonia as the real cause, but I cannot say that I have myself any reason to lay the blame in that direction. I have used ammonia as the alkali with hydroquinone, but though I have now relinquished it in favour of soda or potash, I never remember to have had a single instance of yellow stain with ammonia.

Nor do I recollect to have encountered the trouble when using either caustic potash or caustic soda; but with carbonate of soda I was, for a time, utterly overwhelmed by it—not a mere yellow tinge, but a strong, deep, clear, orange colouration in the shadows of the

negative that completely ruined it for printing purposes. I found eventually, that the result was traceable to and increased with the quantity of bromide employed—that, in fact, when the bromide was altogether dispensed with there was no stain, but that it appeared and became deeper as the restrainer was used and increased. In my case the restrainer was bromide of potassium. I have never tried the experiment with carbonate of potash, but I invariably employ bromide with the caustic alkalis, as I say, without any trouble as regards colouration. Can it be that by some reaction with the bromide of ammonium, in Mr. Cowan's case, some other agent comes into action?

My only objection to the proposed adoption of the metric system is the somewhat Hibernian one that it takes the *metre* as its unit. I have long been strongly in favour of a decimal system, but should prefer the English grain as the unit; indeed, this might be easily adopted without in the least upsetting present methods and customs. All that would be needful would be new sets of weights and graduates, which could be worked and used quite amicably alongside those representing our present scruples, drachms, ounces, pints, and pounds. I myself use, besides our regular apothecaries' and airdupois weights and measures, the French metric system as well as the English decimal system, applying each or any as the particular purpose may seem to require. For instance, if I find it too much trouble to translate a French formula I use the French weights. But I do not recommend the practice to all, and it would certainly be a simplification to resort to a uniform decimal system, but let us adhere to grains.

I recently spoke of the apparent inutility of Mr. C. I. Burton's article on the preservation of solutions of pyrogallol, but in the same number appeared a letter complimenting him in the reverse sense. "W. G." must, I think, however, have taken this indirect but kindly method of suggesting two possible printer's errors; but though sulphate and bisulphate of soda and potash may have been misprinted for sulphite and bisulphite, it would require a small army of most malevolently-disposed "comps" to transform any practically useful preservative into, say, mercuric chloride.

JUNUS.

ORTHOCHROMATIC PLATES IN COPYING OIL PAINTINGS.—II.

In my previous article on this subject I referred to the advisability of those having no experience in this class of work refraining from treating their sensitive plates to a colour bath of their own making. My chief reason for so doing was that they thereby avoid some of the many failures which nearly always attend a first attempt at dipping plates. These troubles take the shape of markings on the film, and the plates are also very liable to contract fog. On the other hand, the plates that are offered by the manufacturers are entirely free from such defects, and, so far as my experience has gone, work clean and nice, any amount of density being got in development.

As a rule, orthochromatic plates are more or less sensitive to all colours, but it must, at the outset, be borne in mind, that notwithstanding that they are sensitive to red, orange, yellow, and green, they are more so to the blue and violet, and once this simple fact is fully understood, it follows of a necessity that an operator must vary his mode of procedure when dealing with objects in which the latter colours are prominent or conspicuous. It is no new thing, however, as many suppose, that some sort of coloured screen is employed to cut down these active rays; such means were employed long ago, before the advent of the rapid dry plate, or the more recent colour-sensitive one. And the advantage of so cutting off the blue ray was known to and appreciated by many workers in the days of collodion.

In many instances, therefore, these yellow screens are of much importance in the work we are considering, and once an operator fully grasps the important part they play in the operation, he will have made no little progress in the mastery of this subject.

From time to time various methods have been employed in the production of and manner of using these yellow screens. There are those who advocate the employment of thin films of gelatine, made to the necessary tint by a suitable dye, and these films are also so prepared as to be of varying depths of tints, so as to act more energetically when the blue and the violet rays are specially prominent. Others there are again who recommend the use of an absolutely white glass which has received a coating of collodion, in which has been dissolved some suitable colour—such as aurantia, eosine, or turmeric.

Another important matter, when discussing the utility of these screens, is as to the best position in which to place them. Here, again, operators differ, and some prefer to use them in front of the lens, others in the diaphragm slot, others behind the lens, others in front of the sensitive plate, while there are those who even go the length of coating a part of the lens combination with a suitable material.

In my practice I have confined myself to two methods of working. The first of these is the placing of a suitably-coloured sheet of glass in the cell of the dark slide which carries the sensitive plate; the other is the placing of the screen in the diaphragm slot. In the latter case, however, I use the screen in such a way as I have never hitherto noticed other writers or workers refer to.

When experimenting with these screens, I at first tried them in front, and then behind the lens, and on my coming to work them between the lenses, I happily hit on a neat little plan, which I think is worthy of more than a passing notice.

In my practice I generally work with a three-quarter-inch stop, and one day when I came to try these yellow screens in the diaphragm slot, it occurred to me that were I to get the three-quarter-inch slot placed in a turning lathe, and a sufficient rebate turned out exactly round the aperture, so as to permit of one-inch micro cover glass being fitted into it, that I would have as good a means as any. So I got an optician to turn out just as much as allowed of the micro cover glass to sit in the rebate, and when after coating a number of these glasses with collodion, in which a sufficiency of turmeric was dissolved to give the necessary depth of colour, I found in practice I had hit on a plan which worked most satisfactorily, and one that gave no trouble at all, so far as fitting on the yellow screen was concerned.

I generally coat about a dozen of these little glasses at a time, and so have always a supply of them at hand, and these vary in depth of tint according to the amount of turmeric in the collodion. These little cover glasses are so exquisitely thin and transparent, and fit so nicely in the rebate on the stop, that the smallest modicum of gum or other adhesive substance holds them firmly in position, and enables the stop to be slipped up or down just as if it were not carrying the screen.

In coating these micro cover glasses there is not nearly as much trouble or difficulty as is the case when it is required to coat, say, a circular screen which is made to fit on the hood of the lens.

I generally take a clean sheet of glass, and by means of my ordinary camera circular spirit level I carefully adjust this sheet of glass, and along the edges of it I place in a row, at convenient distances, these little cover glasses. I then carefully drop in the centre of them just sufficient of the coloured collodion as will, when spread and set, nicely cover the glasses. Should there be any little raggedness at the edges it doesn't matter much, for these will be covered up with the rebate of the stop. This done, I leave them to harden, and keep carefully protected from dust; by this means I obtain a supply of screens of different depth of colour, and at the same time free from specs and imperfections. I know of no medium better adapted for carrying the colour than these exquisitely thin little cover glasses, and they are always obtainable in quantities from any respectable optician.

Those of my readers anxious to try the other methods of using the screens, such as in front of the lens, can get a glazier to fit into the hood of their lens a circular disc; this he will cut with the greatest of ease with his diamond set in a circular gauge, but the coating of these large screens is not by any means so easy as the little cover glasses.

I have done very good work also by using the screen in the same cell as the sensitive plate, but in this case I was fortunate in getting hold of a few very suitable pieces of coloured glass. I have tried over and over again to duplicate these glasses, but have never been able to get a new lot so suitable. It seems to me there is more difficulty in getting these coloured glasses free from specs and flaws than in other kinds of glass.

But this cutting down of the blue or violet ray may be accomplished by other means than the employment of coloured screens, such as a specially prepared glass roof, or window, or other similar means of lighting the object; and where such can be effected, without doubt it is to be preferred to the interposition of the film or glass screen, either in front of the sensitive plate, or in proximity to the lens. One argument in favour of the use of such is the undoubted proneness that a screen has to interfere with the definition of the object being photographed. Whenever a screen is employed, be it in any position, the utmost nicety must be exercised in focussing after the screen has been placed in position. A very little observation will suffice to show the beginner, however, that when adequate means exist of lighting the object with coloured light, such interference of definition does not exist; but it does not fall to the lot of every amateur or casual worker in photography to have at hand such means

of lighting his objects, hence recourse must be had to a screen in some form or other, but whenever it comes into play, special attention must be paid to the focussing.

In my next I hope to treat with what is, perhaps, the most difficult part of the operation, viz., the avoidance of reflections when copying an oil painting.

T. N. ARMSTRONG.

TRANSLATION OF ENGLISH FORMULÆ INTO THE METRIC SYSTEM.

[A Communication to the Photographic Club.]

As requested by the Chairman at the last meeting, I have put on paper the remarks I then made respecting the translation of our old formulæ into the metric system, now definitely adopted by the Club. I am sure to many they will be quite superfluous, but to some few may be acceptable, and as the Photographic Club has now formally decided to use in future only the metric system of weights and measures, I venture again to suggest what I consider one of the simplest methods of translating, with the least possible trouble, any of our existing formulæ.

I take it for granted that every one using any formula has always liked to know what proportion the various constituents in it bear to one another, so that if occasion requires he can vary any of them according to circumstances. In our old system this has generally been expressed by the number of grains or minims contained in each ounce of liquid used—in my own practice, for many years, I have exclusively used the grain as the only unit for both liquids and solids—and I propose to show by an example how formulæ thus expressed is immediately translated into the metric measures, without the figures losing their old familiar look and sound, which they certainly will do if they are literally translated.

For instance, take one of the simplest formula for pyro development, viz.:—

One ounce of liquid containing—

Pyro	2 grains.
Sulphite	8 "
Ammonia	4 "
Bromide	1 grain.

Ten ounces of this of course contains—

Pyro	20 grains.
Sulphite	80 "
Ammonia	40 "
Bromide	10 "

If we now literally translate this it will read—

Pyro	1.296 grammes.
Sulphite	5.184 "
Ammonia	2.592 c.c.
Bromide648 gramme.

Made up with water to a bulk of 233.5 c.c. nearly.

In this form it certainly does not convey to our minds the proportion that each ingredient bears to the others in so definite and simple a manner as does the original formula.

Now what I mentioned last week, and I am almost ashamed to do so again, is to leave the formula alone, and let it translate itself by at once calling all the quantities grammes, when it will read—

Pyro	2 grammes.
Sulphite	8 "
Ammonia	4 " or c.c.
Bromide	1 gramme,

and the bulk of solution 437.5 c.c.

This bulk of solution will be about fifteen times greater than our old-fashioned ounce, but the figures remain almost without fractions, and can be easily multiplied or subdivided if larger or smaller quantities are required.

I have little doubt but that if any one habitually using the metric system had originated such a formula as that used for example, the bulk would have been made up to 500 c.c., or perhaps the amounts of all the ingredients doubled, and made up to 1000 c.c., as I notice in foreign formulæ an almost total absence of the awkward fractions that occur when translating from one system to another.

In connexion with this subject, perhaps I may be allowed to suggest the advisability of always making up the total of any new formula to a definite measure, such as 100, 500, or 1000 c.c., instead of, as is often the case, adding the quantities of the various ingredients to a given bulk of liquid.

ALEXANDER COWAN.

THE LIMITS OF PHOTOGRAPHURE.*

ONE of the beauties of photogravure is the power of giving steady, atmospheric greys. I am not sure that in this great feature it cannot break a lance with every known mode of art reproduction. The extended greys of mezzotint are certainly not better than those of photogravure, but they are very generally worse. I can scarcely call to mind a mezzotint in which the quality of tender atmospheric grey is its one great point. Though I admit its charms of light, yet those lights are small and set up by contrast, whereas in photogravure we get mist whenever we like as well as light. This quality enables the impressionist photographer not only to fix in printing ink the happy triumphs of the camera, but to consult with others and add art to nature's work in the refining of one part, or the strengthening of another part, and thus it must be admitted that a new feature is added to art reproduction in these works. It may be the summer haze over the meadows, or the driving mists of a storm on the coast; they can be caught by the practised impressionist in photography, and they can also be fixed on paper by photogravure in a more living, moving way than by any other mode. This, then, is one special point in the art. Let it be cultivated and encouraged. Nothing pleases men more permanently than a sweetly-rendered aspect of nature, whatever kind of aspect it is—all are welcome in the form of pictures and prints.

There are two branches or classes of picture reproduction in which photogravure shows considerable power. The one is a figure picture, in which clear-cut, well-drawn forms are the chief elements, the smooth surfaces of flesh and drapery lending themselves to the same power that we noticed in the case of the impressionist landscape. The other is where powerful brush work and flashing effects are got, in a manner that labour with a point or scraper can scarcely follow. In both these there is a field for photogravures from pictures.

But in practice I find that oil pictures are the most troublesome of subjects to work from. There is frequently a subtle irregularity in the execution or glazing, or the absence of glazing, the blue-tinted colours; rough touches of the brush afterwards painted over, and many similar things, make it slow and difficult to produce a plate. Although, therefore, one picture may be most happily and beautifully given in photogravure, it does not follow that another will, even though they both look alike in effect, colour, and execution. The camera is a great detective, and it often brings out things that cause much labour to set right. Another fault in a plate from a picture is the want of power to give a whole scale of tints below what it gives as a black. The artist's darkish grey generally comes black on the plate, and then we have to put in by hand several shades of darker tints. This is sometimes a risky and laborious affair.

There may be a dozen different textures and surfaces to render in various plates, and there are as many modes of putting in the colour. For instance, we may use the roulette, which does not go as deep as one would wish; or a small rocker, which is better for depth. Then there is the multiple graver, or the common graver; or a strong etching ground and bite in a lot of etched work, or a re-bite on the old granulations. Thus, added to the trouble of doing the additional work, is the trouble of finding out the most suitable mode. When it is noticed what subtle things will make a method look wrong, it makes one nervous about putting the work in. Big rough points like the teeth of a rasp suit one place; single deep cuts with the graver suit another; and acid on a re-biting ground a third. But it requires years of practice to get the knowledge. Therefore, photogravure should not be regarded as an independent and complete power in itself, but as a new method or means of production, having great beauties when well worked, but not able to meet every case that comes before us in the way of daily requirements.

Seeing that the nature of the original is of importance to know, it would perhaps be welcome to record the results which I have myself noted.

The best working originals are the most seldom obtained in the way of business—viz., oil-painted monochrome, with a steady, solid, impasto treatment. The solid, yet not too solid, effect just suits the process, because it yields a peculiarly agreeable negative.

Perhaps the worst copy usually met with is a water-colour drawing in which much sponging has been used, and where blue is prominent, or neutral tint, with perhaps a warm-looking paper. The vigorous rough Indian-ink sketch is not so intractable by any means, and this must be taken to be what I have already referred to.

A crayon drawing, if not too rough and gritty, also answers well. Some of Holbein's come out very nicely, being most delicately pencilled, and having vigorous portions to bring them out.

Portraits are fairly adapted for reproduction; but it must be remembered that in them we are very captious judges—we want the minutest points in form and shade followed out, as well as a good flesh texture. Portraits from the life are not much better adapted than portraits from painting are. The chromatic changes of the one are only more treacherous than the texture changes in the other. Perhaps the most successful results are those from old mezzotint plates, which always give a level, solid negative containing a slight grain, which is copied from the original mezzotinting.

After these there comes a sort of mixture of difficulties from many sorts

* Concluded from page 384.

of originals; perhaps the most disagreeable of all is a dear old illuminated missal or chronicle, with highly-coloured little pictures. The surface of the vellum is fluff in parts, the colours are uncontrollable, and the work entailed is great. Photographs from nature, such as are commonly executed for sale in favourite localities, also interiors of houses, garden scenes, lead-pencil sketches, sepia drawings, bric-à-brac, and many similar or different things, only present new phrases of difficulty. No two can be dealt with quite alike. The reason being that the eye is very critical, and the camera rather treacherous in the negative it provides for us. I refer at length to these points rather to correct the impression that whatever you ask for in photogravure it is sure to come out prettily.

The point I would specially press, then, is this, that all the methods of photogravure yet practised, when worked at their very best advantage, produce similar results, and the same identical difficulties meet us by whichever mode a plate is produced. One mode does, indeed, differ from another in its power as well as in its method, but the subject in which one fails will most probably fail in another method, and the good subject for one method will be a good subject for another method.

The first efforts at physical photography were said to have been the production of photogravures by the process of printing in a film of bitumen, then, after clearing it, to bite the plate in the clear parts. This mode is still practised on the Continent for line subjects, and it is a tolerable method where skill and patience with good originals and bright daylight combine, but it is practically valueless in England at the present time.

The best line method is that of G. Scamoni, of St. Petersburg, who imparted all its details to me; and though I never gave the care and labour to it that he did, I am sure it is hard to surpass it for line work. The method is to grow a copper plate upon an autotype mould in line. The mould is developed on a surface covered with a fine layer of india-rubber varnish, and it is made conductive by blacklead. The support may be glass, copper, or other metal, not to mention xylonite, which does very well.

This method naturally led up to the desire to get half tones. Scamoni got toned plates from crayon drawings, but not from flat tints. The mode first of all worked was by bronzing a negative or the tissue of which the mould was to be made, and this caused a multitude of punctures in the mould which, when electrotyped, became points in the copper, thus causing the portions of the mould remaining to have various depths. This method now and again gave very fine results, but frequently it failed. Probably, if worked more in the light of modern experience, it would be much better, as in those old days, twelve years ago, we were more anxious to get automatic conduction by means of silver and gold on the surface of the mould than it is now found necessary. It is worth while remarking that plumbago for conducting cannot be excelled, provided all proper means are taken to insure its fineness.

There were also at an early date plates called galvanoplastic. These I know not the method of. They were weak, and required a deal of line-engraver's fine ruling, &c., to put them to rights; they are therefore now quite out of date and also out of memory. But they lead one to refer to the process of Pretsch, which was also practised in England for a time, and which ought to have gone on better than it did. It is worth while mentioning this process as the chief instance of depositing copper on the whole mass of gelatine. There is no mould washed away. It is caused to swell and form an automatic grain, which regulates the tint, and it should be classed with two methods which I will now detail.

The great want of my own bronze-grained plates was that you could not see defects in the plate for some reason, and therefore you could not tell where and how to work on them. I therefore hit on a mode of making a plain autotype mould on a plate, and having no grain at all. This mould or picture was then made sensitive to light again by bichromate of ammonium, and, as soon as dry, it was bronzed all over and exposed to light for fifteen minutes. After the bronze was washed off with benzole, it was put into warm water and the new grain swelled up nicely. I worked this method until I felt the want of true power in it, for it was too fine and velvety at all times, and, for reasons I could not regulate, the grain would vary considerably. But the idea of working from a swelled mould caused me to try moulds of plain sensitised gelatine poured very thin and level on a plate glass, and, after printing them with a toned negative, to print again with bronzed powder on the front; this added a grain just as Pretsch got a grain by chemical means. I was pleased with the result, and went on with it until I found that it could not be made to produce nice flesh tints. It had the much-longed-for property of giving a coarser grain, according as a part got darker, and that was valuable; so also small points of light stood out well, and detail of all kinds, but it was impotent in the very fine greys. The Klick process was then beginning to make a move. About this time Colonel Waterhouse invented a clever grain which we used for some time, and for a certain class of work it was excellent, but its half tones, though powerful, were somewhat dull. The method is to take the mould as it is first washed off, and, while still wet and soft, dust it over with fine sand. Let it dry, and when dry rub the sand off again. The impression left by the sand is very regular and sharp, and it retains its sharpness well during electrotyping, and although it has defects of its own, yet it is a very good method and quick. Its great want is more brilliancy in the dark tones, and also a smoothness in the lightest parts, so that they fail to separate themselves from the pure whites when a number have been printed. The proper mode is to get depth enough in

all parts, and then bring the lights into order by hand work. Another method is coming into practice lately to cure this feebleness in the very light parts. It is to cast over the whole plate a fresh tint by regaining it with resin or bitumen, and biting in with acid until a tone is produced. This tone may be stopped out earlier or later in some parts to save after work, and when all is cleared off a proof is taken, and the lights are put into order by hand work. This procedure also improves the darks of many plates by steadying them. The new grain generally settles on the old prominences of copper, so that the effect is to deepen the old work and not to confuse it. Moreover, the two degrees of tint, where they do come together, or one upon the other, are mutually helpful, and give the look of mystery and depth so often valuable. One depth or one layer of tone generally has a hard and prominent effect, but a double tint looks soft and suggestive. This quality was noticed by the old mezzotint engravers, who very often laid a fresh ground over a plate, which to the ordinary person looked finished; then they had all their work to scrape up again, but the plate was rich in proportion and worth the extra trouble.

This is a proper time to describe another great want of all natural photogravure plates. It is quite absurd to suppose that what a negative has not the power to get, the copper plate made from it shall have. It is, however, very wise to gently work up a negative or transparency to effect that which nature cannot do for it. There are various methods of doing this. If rough texture in parts is desirable, the glass may be matt-varnished on the picture side and the crayon applied on the grain. But if gentle tints are wanted, then the other side should be worked upon. It is, however, often noticeable that when the plate is produced, the hand work is too heavy or misapplied, and it is too late to go back again. This sort of work is most called for in the dark portions of a subject, and it is best not to try too much in other parts.

When this is done, however, it is often only too plain that we have not depth enough in the plate. When an oil painting is placed against a print, it is easily seen that our scale is much shorter than the oil painting; therefore, an abundant power in reserve to give depth and power to the plate is advantageous, so that the printer need not make an opaque heavy ink to get the print right.

The printer's ink should always bear some dilution for the start of a plate, and also for the reason that it is so common that a dark dull solidity comes from a plate having no real depth in it, yet plenty of middling dark. I have seen a plate of Goupil's (whose process I have not further gone into, beautiful though it often is) brought well out by deep etching with acid on the top of the other tint, the lines of the etching being bitten as usual through a strong ground laid on. It is difficult to really blend etching with the tint, but if contrast is called for it will do. Some form of graver is better, because you regulate its depth so instinctively to the needs of each part of the work.

The lighter portions and the use of dry-point work, together with the scraper and burnisher in finishing, are too simple to need any time being spent on their description.

Printing deserves a word. I have found that careful work with the best possible materials is most essential. A paper with a coarse fibre, however excellent otherwise, will never do for photogravures. So, too, size must not be allowed. Thus the paper admired for etchings is quite unable to print photogravures; it is harder in texture and rough, so that it cannot enter into the tiny pits in the process plate. This is unfortunate, because the presence of size greatly adds to the brilliancy of the darks in a print, and that is what we most need from the process plate. However, we have to put up with the colour obtainable on an absorbent paper.

It is worth while, before concluding, to touch upon the field and opening for photogravures. It cannot be contended that every subject is best done on this plan; and as the taste of men will from time to time demand every kind of subject, it must be evident that it will rest with us to confine our efforts to such subjects as have been proved to succeed best. In the matter of publication plates, there are so many fine etchings and such very fair autotypes obtainable that the method of photogravure wants to be particularly guarded from betrayal by some mistaken choice of a thing that will cost much labour and then turn out a failure. In plates for books, and in those folios of pictures from some locality now so frequently seen, it cannot hurt so much if there are partial failures, because they are not exposed to the public view so constantly, and also because if there is a failure there will also be several successes in the same lot.

One mode of use applicable to all kinds of printed books is to leave the space for a picture blank in the printing, and have the pictures printed on a thin India paper elsewhere—perhaps six, or eight, or ten together; these are cut up and pasted in the book at their right places. Mr. Linton's important work, *The Masters of Wood Engraving*, is almost entirely photogravure, and the prints being treated as above look very natural, and fit in most easily without the least harm to the printed book itself, while it is not easy to ascertain that they are produced by an intaglio process at all. Yet the peculiar advantages of the process come out in the result, for the experts are said to wonder how it is that these reproductions are superior to the originals.

Of course, for artistic effects of great power this method is equally applicable, and it is well known that these finer efforts are the very ones that most distress printers and producers of books. Yet it is on these alone that the public sets the greatest value.

I hope I have not been too long and prolix in this little essay on so modern and interesting a subject. It appeared to me far more suitable to

the requirements of all that the result of my own efforts in this branch should form the chief body of the paper, rather than to go into purely technical details and questions, which are all very interesting to a very few, but which experience has taught me are quite discounted by the insatiable public on the one hand, and by the infinite demands of art on the other.

SALFORD PHOTOGRAPHIC EXHIBITION.

A PHOTOGRAPHIC Exhibition was opened on Thursday last at the Peel Park Royal Museum, Salford, by the Mayor of Salford, Mr. Alderman Dickens.

Mr. Alderman Bowes, the Chairman of the Parks Committee, after calling attention to some of the principal exhibits, regretted no society of photographers existed in the borough, and hoped the exhibition would be the means of promoting such a society. Considering the very limited time that was given for the preparation of exhibits, a very creditable collection has been gathered together, filling two rooms. To photographers, perhaps the most interesting contribution at the present time will be a series of twenty-five or thirty portraits by the late Mrs. Cameron, of Ventnor. They are lent by the Parks Committee, and comprise, amongst others, portraits of Thomas Carlyle and Mr. G. F. Watts, exhibiting very clearly Mrs. Cameron's peculiarities of treatment. Messrs. Barrand sends portraits of Mr. and Mrs. Kendal, Mrs. Bernard Beere, and other celebrities. Mr. Warwick Brookes, of Manchester, has some excellent portraits, including Henry Irving, Leo Tyklynsky, Edwin Waugh, and an extremely delicate photo-engraving of Miss Nellie Murray. Mr. La Fosse and Mr. John White are represented by enlarged portraits of the Mayor and ex-Mayor of Salford.

In landscape work a prominent place is accorded to a series of twenty-seven views of the engineering workings of the Manchester Ship Canal, lent by the Engineer to the Ship Canal Company. These are by Mr. H. Garnde, and have never been shown in public before. The same gentleman has also a large series of views of the galleries and grounds of the Manchester Jubilee Exhibition. Local amateurs naturally come most strongly to the front in views of choice bits of scenery. Mr. James Wood sends ten frames of Obernetter prints, which are remarkable for their artistic taste. Mr. W. Faulkner sends twelve interesting frames. Mr. James Higson's landscapes lose some of their effect by the gilt framing, and some of Mr. Tomlinson's would gain by more attention in the mounting. Transparencies are exhibited by Mr. W. I. Chadwick, Hon. Secretary of the Manchester Photographic Society, and Mr. James Higson.

FIGURES IN LANDSCAPE AND GENRE.

[Paper read by Mr. Graham Balfour, M.A., at the Camera Club.]

THE employment of models in photography is, perhaps, verbally a more exact title for the remarks which I propose to make to-night, but that seems somehow to have a more utilitarian, at once a more mechanical and more practical ring than can belong to any hints of mine, and therefore I have asked you to listen to a few suggestions on the use of figures in landscape and genre.

This limitation will, at any rate, serve to show that I refer only to those photographs which are taken as pictures for their own sake. I do not deal with illustrations of places or people, nor with scientific work, but solely with original photographs taken for the intrinsic beauty or interest of the subject, as visibly expressed or actually suggested in the print, and carried to the utmost perfection possible to the means employed.

I assume that the pictures are satisfactory in composition and tone, that they are correctly exposed, happily developed, and suitably printed, for none of these points am I now going to discuss.

In landscapes the necessity for figures is a vexed question, and one with which I at first intended to begin this paper. But it is too wide and important a subject to touch merely as a side issue, and I will here simply state my own opinion that, with two or three obvious exceptions, landscape without the figure of man or beast is a mistake, and that the result of such an omission is want of purpose and of interest.

Genre painting, at any rate, always includes figures, except in those pictures of still life, drawn mostly from the dinner-table and the larder, which are so uninteresting in colour, and in photography fortunately are seldom seen. The exact content of genre is defined by Littré as painting other than historical or landscape, and certainly those are the three classes of the old division of the art. But portraits I would now place in a class by themselves, or, at any rate, exclude from the following remarks, and with the still-life portion of genre I have evidently no concern.

Thus for genre, as the domain of character and incident, I presuppose figures, but the border-line between it and landscape with figures is notoriously hard to draw. Probably no scientific frontier is possible; roughly, the division is made by the size of the figures and the expression of the face, accordingly as it is visible or otherwise. I attempted a classification on the basis of visible expression, but it would not hold, and fortunately an exact definition is here unnecessary. The same rules apply in each case. On the size of the figure chiefly depend the uses to which we put it, the purposes for which we employ it. The smallest

figures are generally introduced as a spot in composition, or to save the picture from being entirely inhuman and desolate. Slightly larger figures, which are still too small to exhibit the expression of the face, yet tell their story by gesture or attitude. Most of the rules relating to facial expression apply equally to gesture, and therefore I pass on, merely noticing that the smaller the figures are, the less effect do they produce, but, at the same time, they are easier and less intractable; for, when the face is not seen the figure is much simpler to pose, and even if the attitude is slightly strained or self-conscious this fault is less conspicuous, and any shortcomings of costume or model are less glaring. Thence we pass into the debateable land where the figures are of exactly equal importance with their surroundings, and the boundary question is mostly settled by prejudice. Beyond this comes the region where figures are all-in-all, and the landscape dwindles away into nonentity. I believe that the whole of this continent is under the same laws, but that the different rules differ in importance in various provinces. To drop metaphor, it is manifest that the larger and more distinct the face is, the greater is the care required in dealing with it.

Most of the general rules of art which can be laid down for the guidance of photographers can be discovered by common sense, and most of the crimes committed in the name of photography are due rather to want of reflection than to deliberate depravity. Many photographers, especially the scientific workers, have a horror of art rules, which they consider altogether unnecessary and arbitrary. It is a fact that once a truth has been decanted into a certain form of words, it has necessarily ceased to be the whole truth, for there is always some leakage and some change in the process. All formulated maxims are very condensed records of experience, and are of little other use than to serve as hints and suggestions, mostly on the prohibitive side. Law making is the first conscious stage of any art, but unless the set forms are sooner or later altered, modified, adapted, and at times broken, that art is incapable of any further progress. Nevertheless, in the dearest formula always there has once been a germ of life, and to preserve this and render it once again useful is the best service any critic could perform. But my point is, that most of the rules of art were not in the beginning mere pedantry and charlatanism, but fresh, vital, and pregnant discoveries.

It is, again, supposed to be cramping and destructive of life and enterprise. An art that is as full of stupid signboards as Mr. Du Maurier's picture of Hampstead Heath is neither pleasant nor profitable. I only hope that I may never say anything that will discourage energy or new departures. Experiment is the life of art, especially of a new art. Genius generally disproves a few rules. If you think you see a new line, consider it fully, then have a dash at it, then see where you have got to. Only, if you fail, for art's sake do not ask any one to believe that you have succeeded, or to follow you. There are wrong ways as well as right ways, and if you can discover which is which, it is only a waste of time to start on the former. Let us proceed to see what directions we can lay down for photography.

I. The first thing to inquire in any art is, What is its aim, and what means has it to carry out that aim? If we discover these means and their capabilities, and do not attempt to overstrain them, we are not likely to go far wrong in that art.

Now every photograph, so far as it is a photograph in any present sense, has been produced by two agencies—by the joint action of man and his apparatus—by the human and artistic element, and by the mechanical and scientific element.

It is thus plain that there are two sets of limitations in photography, and consequently two sets of rules which have to be taken into account.

I will first take the material limitation, the restricted powers of the camera and lens. Now the worst point about a lens is that it has little or no imagination, but is so very matter-of-fact. It sees truly, but it can see nothing but what is just in front of it in an actual, material shape. Thus (a) it can only deal with the present; the past is useless to it, and though a perfect observer and recorder of passing events, it is useless for retrospect. It writes chronicles, not history. (b) It can do no ideal or imaginary work.

Next let us consider the restrictions of the artist himself. The human eye and brain preside over all art. Using other means than the camera, they can call up the past and reclothe it with visible form, or give outward embodiment to ideas which have only existed in the mind, or select certain out of many objects in the scene before the eye and represent these alone, to the exclusion of all else. But the human retina is in some ways less perfect than the lens and gelatino-bromide plate. As far as light is concerned, they are fairly equal, though the right kind of light is cumulative for the plate, which thus in time records what the eye can never see. But as far as art is concerned, the chief difference lies in the power of receiving instantaneous impressions. The lens and plate can record attitudes and effects which the eye can never perceive; and what the eye cannot see in nature, it naturally refuses to recognise in art.

Thus from artistic photographs we must exclude, on the one hand, what does not exist in outward nature, and, therefore, can never itself be transmitted through the lens; and, on the other hand, certain actually existing facts discovered by the lens, yet which the eye can never see, and consequently would never select for a picture.

Now it may be asked why we should concern ourselves with the nature of the means, and why we may not use any results we can obtain and be thankful.

As to the limitation of the human eye, I can only say that art in its present meaning depends upon the human observation of nature. If you develop an art based on instantaneous photography, you embark in an altogether new and distinct enterprise, and you have my best wishes for your enjoyment and success. But you have no connexion with art as it now exists.

As to mechanical limitations, the argument that the end is all in all, and that any means may be employed to reach it, is the one which has been heard oftenest in the battle between the two styles of wood-cutting, the old and the new, the schools represented respectively by Bewick and the *Century Magazine*. The essential feature of wood-engraving is, of course, that it is portion of the woodblock cut away which is rendered white in the print, whereas in metal plates every cut is printed black. Consequently the white line has been treated as the characteristic of the woodcut, and upon it the old craftsmen relied for their effects, while the new school, on the other hand, has set itself to produce masses of half tone with a great variety and delicacy of gradation. The former declare that this may be beautiful, but it is not of the nature of genuine wood-cutting. The young men answer: "That may be true, but what do we care? As long as our results are admirable we will continue to produce them by any means in our power."

I am not responsible for the defence of the new wood-cutting, but, as a matter of fact, I consider it to be quite legitimate, because the white line is not so absolutely essential a part of the prints from woodblocks that any reproach is due to the artists who neglect it. To the outsider any one mode of cutting, if it is fairly within the power of artist and tool, seems as good as another, if the impressions are equal. As long as the change of method does not result in a deteriorated product, greater freedom of working conditions must be a benefit to the art at large.

But with us in this instance it is otherwise. Reality is so invariable a condition of photography that it is inextricably bound up alike with end and means. A photograph cannot be a photograph at all in my present sense unless it has been taken from a real object. It is no case of alternative treatments, which both issue in a legitimate result; but here if the making is conducted on wrong and dishonest principles, the thing made is inherently bad.

I do not wish to introduce any irrelevant philosophy, but may remark that all this artistic morality is quite different from the private morality of the operator, and that transgression of it merely vitiates the product in which such artistic fraud appears. I bring this in because I believe that a good deal of harm has been done to art by the supposed identity of æsthetic and ethical morality; I am certain, at any rate, that a great deal of nonsense has been talked about it; but here I am careful to recognise the distinction, and speak only in terms of art. An art has certain limitations, that is obvious. If it go beyond them by some trick, and produce a result which cannot be what it pretends to be, and only passes because it is a result possible to some other art—that is artistic dishonesty. Not only must it be in the long run unprofitable and disadvantageous, but it cannot have any real and honourable life of its own.

This, of course, does not exclude "dodges," double printings, and the like, which are but remedies applied to the shortcomings of our tools, *provided always* that the results are *more and not less true to nature* than they would otherwise have been, and are consistent with the means which must have been employed to produce them.

Now let us leave these rather dreary generalities and examine in detail a few concrete offences against Reality. This will fall into two divisions—Human, the reality visible to the eye; and Mechanical, the reality confrontable by the camera.

As to Human Reality, there are certain subjects to which it is advisable or necessary to give very rapid exposures, such as animals, the use of which I shall recommend later on. Now, in instantaneous pictures we have to be very careful of our attitudes. Whence man originally derived the idea of the gait of horses, such as we see expressed in pictures, I do not know; I suppose they are, after all, "impressions," that having, like a Japanese artist, carefully studied the animal in motion, the painter then sat down to produce the four legs in attitudes which should give a general effect of its action, and some one early version was adopted as the pattern which, with occasional slight modifications, was followed for centuries. So little capable was the human eye of following such rapid motion, that, as you will find in the Badminton volume on racing, Dick Christian, a man conversant with horses all his life, stated and firmly believed a theory that, after a jump, a horse always alighted on its hind legs.

Some of the attitudes discovered by photography were entirely novel and incongruous, possible only to rapidly-moving bodies, and that for a brief instant; others do not differ so widely from the accepted conventionalities: and these, being the representative and typical parts of the action, we are gradually being educated to adopt. I have noticed, for example, that Mr. Gow is always very careful in the horses in his fine battle pictures to employ attitudes alike truthful and graceful, though I do not know anything about his methods.

But, unfortunately, this fact leaves the success of a good many of our photographs to mere chance, since a moving animal in a prominent spot may come out in a ludicrous neck-and-crop attitude, at once incongruous and apparently impossible. Even the walk of a cow, for example, I have

always found to be more ungainly than would have been imagined. Homer's "trailing-looted" oxen are certainly better seen at rest than in motion. Where the figures are very small, the defect is so inconspicuous as to be outweighed by the advantages of the figures; but for pictorial effects it is better if possible to avoid those attitudes which cannot be maintained long enough to become visible to the human eye; and if there is no help for it, we must just take our chances, and pick our results.

(To be continued.)

CAMERA CLUB CONFERENCE PAPERS.

SOMETHING NEW IN PHOTO-LITHOGRAPHIC WORK.

By W. T. WILKINSON.

THE usual method of making photo-lithographic transfers is upon gelatine made sensitive with potassium bichromate. This is quite sensitive enough to daylight, or to electric light; but if transfers are required when neither day nor electric light is available, then bichromated gelatine is useless, and some other method is wanted. Try this:—Make a print upon any of the ordinary bromide papers of commerce, using a good negative from a subject in line, by artificial light; develop the image with alkaline pyro, then wash and place it upon the inking-board (see fig. 16, p. 141, *Photo-engraving, Etching, &c.*); next, blot off the water with a soft cloth, and dab all over with a sponge saturated with transfer ink thinned with turpentine; let the turpentine evaporate, then take a glue roller, *i.e.*, a type-printer's roller, and roll until the whites are quite clear of ink. Now soak the print in the pyro again for a few seconds, and expose it to the light. Finally, wash free from pyro and hang the print up to dry. When the print is dry it is ready for the transferer, who treats it the same as he would any other photo-lithographic transfer.

The only way to fail with this method is to over or under expose the print, or to use a bad negative. The negative must show perfectly clear lines. Some of the newer papers of commerce contain too little gelatine to succeed perfectly, therefore it is best to make the paper at home. It is not a very complicated process, as the colour of the image under the developer is not all-important. A good formula is—

Gelatine	800 grains.
Water	30 ounces.

When the gelatine is quite soft melt it at 120° Fahr., and add 320 grains of ammonium bromide; stir it until it is dissolved, then add ten minims of hydrochloric acid and stir well.

In ten ounces of water dissolve 450 grains of nitrate of silver, bringing this solution to the same temperature as the gelatine solution; now proceed to pour the silver solution into the gelatine in a very thin stream, stirring it vigorously all the time. Now strain it into a warm dish, and tilt the solution so that it is only along one edge of the dish. Having made a small roll of the paper, lay one edge of the roll upon the liquid, and as it curls take hold of it and lift it slowly up, when the paper will unroll itself, and receive a nice even coat of emulsion. Hang it up to dry, and repeat until all the emulsion is used.

For half-tone transfers use the bromide and chloride of calcium with 200 grains extra of gelatine, drying the paper at as high a temperature as possible without melting the gelatine. Paper with this emulsion upon will be very hygroscopic, and must be kept very dry. Before use always dry the paper, and warm again before developing, so as to encourage the reticulation of the gelatine.

This paper is to be exposed under a half-tone negative, developed and washed, then inked up as directed for the line transfers, followed by immersion in the developer, and subsequent exposure to light, washing, and drying. To transfer to stone, trim with a pair of long shears, then put it into the damping-book until quite limp; then sponge the back of the transfer with a solution of oxalic acid one part, water 100 parts. Take great care that none of this solution gets on the front of the transfer. Lay the sheet in position upon a cold, dry stone, and pull it through the press, with plenty of pressure, five or six times without lifting the tympan. The paper can be lifted off, leaving the image in ink on the stone. Gum it in and leave it for five or six hours before rolling up.

TO MAKE GRAINED NEGATIVES FOR ZINC ETCHING WITHOUT A SCREEN.

By W. T. WILKINSON.

THIS is done by coating the plates with an emulsion containing sulphate of baryta in very fine powder, and well shaken up before coating. Pictures are taken upon these plates and developed and fixed in the usual way, but the image instead of being smooth and nice will be covered with myriads of fine pinholes. These negatives are used for printing on the zinc in bitumen, then etched in relief for type blocks.

Instead of sulphate of baryta, carbonate of soda, &c., may be used in the emulsion, and, after fixing, immersion in weak acid will develop the pinholes. The bromo-chloride emulsion may be used upon collotype

PATENT COMPLETED.

APPARATUS FOR AUTOMATICALLY PRODUCING AND COMPLETING PHOTOGRAPHS.

No. 5211. KARL RAMSPECK and BARTHOLOMÄUS SCHÄFER, 2^{te} Jacobstrasse, Hamburg, Germany.—*March 26, 1889.*

THE object of this invention is an apparatus which shall be capable of producing and completing automatically the photographic likeness of persons.

The essential features of the apparatus are that a motor, actuated by clockwork, by weights, or by electricity, or otherwise, revolves an upright shaft arranged in a closed box or casing. The shaft carries a radial arm attached thereto, at the end of which is a holder which seizes a plate at its upper end shifted forward from a conveying apparatus. The plate is revolved by the rotating shaft, and during this rotation it receives the necessary preparation for producing the photographs as well as the further treatment after exposure necessary for developing and fixing the picture. This is done in the following manner: During revolution of the shaft, the arm carrying the plate dips the latter by corresponding downward movements first into a solution of collodium and then into a bath of nitrate of silver. The plate thus prepared arrives in course of the further revolution of the shaft in front of the lens, and during a short stoppage of the arm in front of the said lens, a shutter opens and the plate is exposed. The plate then continues its movement, and is successively brought in front of several syringing and rinsing apparatus. Finally the picture is immersed in a solution of lac and quickly dried. The baths arranged underneath the arm are in basins in a circle around the shaft.

Instead of carrying the plate around the circle, the baths can be revolved by attaching them to the vertical axis; the plate then only moves up and down. The intervals of time which are necessary for the immersion and the remaining of the plates in the baths and for the stopping in front of the lens are regulated by the motor.

[A drawing of an apparatus is given with revolving vertical shaft.]

The claims are:—1. In apparatus for automatically producing photographs the construction whereby the series of various operating agents are arranged in a circle about a central holder, in which the plate to be treated is supported so that said plate may be brought under successive operation of said agents for the production thereon of a photograph, by the rotation of said holder or of said series of operating agents.—2. In apparatus of the nature set forth in claim 1 for automatically producing photographs, the construction of the plate holder and of the several mechanisms for performing the stages of the process in combination with said holder, substantially as illustrated and described.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

JUNE 11.—Mr. James Glaisher (President) in the chair.

The PRESIDENT announced that the Judges elected to act at the next Exhibition of the Society are Messrs. Bedford, Blanchard, Davison, W. England, Gale, Robinson, and Taylor; and that they would also act as the Hanging Committee, so would have full opportunities for studying the merits of the pictures.

Mr. T. R. DALLMEYER read a paper on *The Bearings of the Possible Introduction of Spherical Aberration in Photographic Lenses*. He said that the amount of foreground requiring to be brought into comparative sharp focus in photographs is less than the amount beyond the chief object focussed, and that softness and delicacy are given by the introduction of a certain amount of spherical aberration. His late father made a portrait lens which would suit both purposes, in consequence of the demand for such a lens by some of the

leading photographers, although there are widely divided schools among photographers in relation to this subject.

Mr. W. E. DEBENHAM said that the plan of introducing spherical aberration was proposed by Professor Petzval about 1858, but the Professor said that it did not give more sharpness in the outer planes; they looked sharper because there was no sharpness with which to compare them. Mr. Dallmeyer now claimed that sharpness was improved only on one side of the sharpest focus; he (the speaker) had tried experiments on this point and found that it was not the case. If Mr. Dallmeyer's contention could be supported it should be proved by experiment.

Mr. CHAPMAN JONES remarked that some of the best photographers accepted the lens as useful, and that was a proof that it was wanted. He thought that the points of contention between the late Mr. Dallmeyer and the late Mr. Grubb were both proved by the published diagram of the latter, for the image consisted both of nucleus and halo, wherefore he thought it impossible to test the point, which could best be decided by practical experience with the lenses.

Mr. DEBENHAM was not at variance with those who liked spherical aberration. Mr. DALLMEYER replied that Mr. Debenham's method of testing was not quite a fair one; it was best to test by means of the image of a candle flame.

Mr. DEBENHAM suggested that Mr. Dallmeyer should repeat his experiments, but use a black spot on a white ground instead of a candle flame, and that then he might not obtain the same result.

Mr. DALLMEYER responded that with a flame it was easier to see when it was in or out of focus.

Mr. LEON WARNERKE said that he had had a visit from a Russian gentleman who had given him a few small pieces of a new printing paper made by Mr. Suchatcheff, of St. Petersburg. He (Mr. Warnerke) did not know how the paper was made. It required, he said, a little less exposure behind the negative than does ordinary albumenised paper, after which the image may or may not be visible; it is then developed by floating the back of the paper on water, and afterwards fixed by pushing the paper below the surface of the water and washing out the salts. He had found that there was no silver in the paper, and that a trace of hyposulphite of soda in the washing water improved the colour of the prints. The speaker then developed two prints which, by the aid of the hyposulphite, were of a kind of violet-black colour. One print was from a negative he had taken in Constantinople last year; he had not been hindered when taking open-air photographs in that city.

Mr. DEBENHAM thought that the paper might have been prepared with an iron salt in conjunction with a salt of palladium, iridium, or gold; probably gold.

Mr. WARNERKE thought that there was no gold in the paper, which was made commercially for copying engineering and other plans.

Mr. W. H. HARRISON supposed that a bichromate salt might be the chief agent; the colour first produced resembled that due to the reduction of a bichromate by light, but was deeper.

Mr. JOHN SPILLER suspected it to be prepared with mixed gold and iron salts.

Mr. WARNERKE speculated that a uranium salt might be the chief acting agent.

Mr. Friese Greene exhibited a photograph which had been printed and fixed on a card made waterproof, so needed no mounting.

Mr. WARNERKE exhibited a flash-light picture of the previous Council meeting, and suggested that one should be taken by somebody of every Council meeting throughout the year.

The PRESIDENT hoped that photographers would do their best to send in many good photographs for the coming Exhibition of the Society.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

JUNE 6.—Mr. F. A. Bridge in the chair.

Mr. H. B. Scott was elected a member.

Mr. H. D. ATKINSON exhibited some prints which had been given to him as old photographs; from their appearance he thought that they were among the earlier productions of the Stereoscopic Company.

Mr. W. E. DEBENHAM thought that they dated from 1857 or 1858.

Mr. HERBERT S. STARNES exhibited two large volumes of old photographs, dated 1855 and 1857, which had been lent to him by Mr. J. J. Morrish; the volumes consisted of "Contributions of the Members of the Photographic Club," and were published by Charles Wittingham, London, under the title of *The Photographic Album* for the particular year in which each volume was issued. Mr. Starnes added that the process by which each picture had been taken had been printed in these volumes opposite each print; if the same plan were to be adopted now the prints of our own day might be very useful twenty or thirty years hence. The more permanent of the photographs in the volumes had been printed on Twogood's plain paper by the ammonio-nitrate process and toned with *sel d'or*. The albumenised prints had yellowed considerably. He added that the most faded prints in the book had been taken by professional photographers.

Mr. DEBENHAM stated that *sel d'or* certainly favoured permanency but that it did not answer with albumenised paper; *sel d'or* consisted of hyposulphite of gold, and it yellowed albumenised prints. It threw down much gold on the print, and that was a great advantage, because it thereby gave greater permanency. A photograph in one of the books from a calotype negative showed no halation in a window in the picture.

Mr. W. H. HARRISON noticed that two of the pictures in the volumes had been taken by Sir Joscelyn Coghill, the father of one of the two young officers who were killed in Zululand fighting for the Queen's colours; one of the pictures was the Castle of Chillon and the other the Gorge of Gondo, in Switzerland; both pictures were dated 1855. Sir Joscelyn Coghill had told him that he could take photographs, but said so in such a modest way that he (the speaker) had no idea that he could do such good work by old processes as in the specimens on the table.

Mr. P. EVERETT had a lens which threw an image so that when distant objects were out of focus the motion of the shutter behind the lens seemed to make those distant objects move up and down.

Mr. DEBENHAM remarked that the "out of sharpness" meant that every point occupied considerable space on the plate, and the shutter in its motion cut off successively different parts of the diffused image.

NORTH LONDON PHOTOGRAPHIC SOCIETY.

JUNE 4.—Mr. J. Traill Taylor (President) in the chair.

Rev. E. HEALY showed some plates by Kennett which he had developed; they were about thirteen years old.

Mr. W. BISHOP asked what difference there is between bromide of potassium and bromide of ammonium.

Mr. V. BLANCHARD stated that when using bromide of ammonium with the hydroquinone developer a yellow stain is produced, while no stain is present with bromide of potassium.

Mr. A. MACKIE said that with pyro, bromide of ammonium is a more powerful restrainer; some plates, however, are more liable to green fog with it.

Mr. Blanchard was then called upon to demonstrate his new method of toning prints with platinum, several prints toned by this means having been exhibited to the meeting.

Mr. BLANCHARD commenced his remarks by showing two negatives which were the thinnest that good prints could be obtained from, and said that the chief cause of failure with beginners is under printing, as the prints reduce considerably during toning. He then toned two prints which had not been quite printed enough, and successfully accomplished it by stopping the toning at a warm black before too much reduction had taken place. So much platinum is not deposited on the print by stopping the process early, and the printing must be continued to allow the platinum to go right through to obtain good black tones, which were considered much more artistic. He had been using a rough-surface thick paper, which produced results much more artistic than the glass and warm colour of the silver print. Fifty years ago photographs on matt-surface paper were considered correct from an artistic point of view, and, after photographs with a glazed surface had been in vogue for many years, the public were again coming to the belief that a matt surface is more satisfactory. They were indebted for this in a great measure to Mr. Willis for the invention of the platinotype process, but he claimed for his process that combination printing can be done much more easily than with platinotype or other papers that do not print out. It would print quicker than albumenised paper, and he considered that if it were cut up and kept between glass it would be good in two years; it was also a very simple and workable process.

Exposed prints having been handed round, they were washed as ordinary silver prints and placed in the toning solution containing the platinum and fixed in hypo, one to six, for ten minutes.

Mr. W. BISHOP asked if there would be a loss of permanency in stopping the toning early to compensate for under printing.

Mr. BLANCHARD replied that as there is no sulphur compound in the paper as in albumenised paper, they would probably be just as permanent under ordinary conditions.

The next meeting will be on June 18.

EAST DULWICH AND PECKHAM PHOTOGRAPHIC SOCIETY.

JUNE 7.—Mr. F. W. Webb in the chair.

Mr. F. W. EDWARDS gave a demonstration in *Platinotype Printing*. He fully explained the platinotype process, and having brought with him about thirty undeveloped prints, proceeded to develop them before the meeting. The greatest enemy to success being damp, Mr. Edwards purposely left a print to show what the effect would be if damp was allowed to get at the paper while it was being manipulated. The whole of the demonstration was very successful.

It was resolved that an outdoor meeting be held on Saturday, June 22, in the neighbourhood of Carshalton, the members to assemble at half-past six for tea at Cheam Park.

The next ordinary meeting will be held at 76, Peckham-rye on Friday, July 5, at eight p.m.

NORTH SURREY PHOTOGRAPHIC SOCIETY.

JUNE 4.—Messrs. W. H. Walker and Lewis Wolff were elected first President and Vice-President respectively.

The members are to be congratulated on their selection to fill these offices; both gentlemen took a large share in the formation of the Society, in January, 1887, and have never relaxed their exertions for its welfare.

A discussion on hand cameras followed the election. The HON. SECRETARY made a few introductory remarks, classing this form of camera under two heads, viz. purely "detective" cameras, and those that may be used in the hand without attracting attention or on the tripod in the usual way. Messrs. Marjion's book and parcel detectors were then explained; the Kodak, having been already shown, was not again explained.

Mr. FALLOWFIELD then described the method of working Miall's new camera, the chief feature of which lies in the means of changing the plates by a turn of a button, the change being registered on a plainly visible disc above the button. The low price of this instrument is very noteworthy.

Messrs. Thomas's "Wellington" was kindly sent for the members' inspection, and a representative of the firm explained its points. The use of double backs is applied to this camera; and two of similar construction, by Messrs. Watson and Messrs. Beck, were brought by members and placed on the table.

Messrs. Rouch's "Eureka" was explained, and samples of work done submitted. This was followed by the "McKellen," comment being made on the method of focussing applied.

Mr. H. Sealer submitted an American pattern which he had considerably altered and improved.

The Hon. Secretary also showed Messrs. Hockin's "American," for use with films; its principle feature was considered to be its exceptionally low price.

Considerable discussion arose on the various forms of camera, and the time at the disposal of the meeting was hardly sufficient for the full consideration of this wide question, which will probably be revived at some future date.

At the next meeting, on the 15th instant, at the West Norwood Constitutional

Club, at eight p.m., Mr. Valentine Blanchard will demonstrate his new black platinum printing process. Visitors welcomed.

BRIGHTON PHOTOGRAPHIC SOCIETY.

JUNE 11.—The President in the chair.

A discussion on *Hydroquinone as a Developer* was opened by Dr. REAN, and the subject was warmly discussed by the members present.

The negatives and prints of the views taken on the Rottingdean excursion were then exhibited, also several prints and negatives the work of members.

Next excursion to Lewes, Saturday, June 22. Train leaves the Brighton terminus at twenty-eight minutes to three p.m.

Mr. E. J. Bedford will read a paper on July 9 on *The Art Side of Photography*.

LEWES PHOTOGRAPHIC SOCIETY.

JUNE 4.—The President in the chair.

Mr. A. H. C. CORDER read a paper on *The Platinotype Process*. His paper dealt briefly with the hot and cold-bath processes, the Pizzighelli direct printing process, and the new process just brought out by Mr. Valentine Blanchard. He afterwards developed some prints by the hot-bath process and passed them round for inspection.

A discussion then took place, in which the President, Mr. C. A. Wells, Mr. Foxall, the Hon. Secretary, and others took part.

The meeting then resolved itself into a *conversazione*.

Several members brought negatives obtained at the excursion held on May 20, also prints from them, and, considering the unfavourable weather, the results were considered satisfactory.

The President exhibited his detective camera, which consisted of a quarter-plate camera in a box, and showed work which had been done with it.

Several other members also exhibited work.

At the next meeting, to be held on July 2, the Hon. Secretary will read a paper on *The Artistic Side of Photography*.

SHEFFIELD CAMERA CLUB.

JUNE 7.—Dr. T. H. Morton presided.

Mr. Claude Barker was elected a member.

Several interesting objects were shown, including Carbutt films, stereoscopic views by Mr. G. E. Maleham, instantaneous studies by Mr. J. O. Arnold, F.C.S., also a number of views taken with a drop shutter by the Chairman on Edwards's isochromatic plates; the density and detail in the negatives proved the efficiency of this class of plate.

Mr. ARNOLD then gave a lecture on *Photo-micrography*. He described the apparatus necessary, and mentioned the difficulties which beset the process in its various stages. He said it was essential to have a powerful and steady light, and for moderately dense objects he used a good microscopical lamp with plano-convex condenser, but found limelight and magnesium ribbon more effectual. Transparent sections of wood and tissues generally were best stained brown or red, that is in their structural details; blue stains and pale tints gave very poor results. Opaque bodies, including many rock sections, had to be taken by reflected light, and Dr. Sorby's hyperbolic condenser was invaluable, as it threw no shadow. In regard to the microscope, the lecturer worked with both objective and eyepiece. The power selected depended on the subject; two-inch up to quarter-inch embraced a large number of suitable objects, but a higher magnifier was occasionally needed. Mr. Arnold proceeded to photograph a specimen of mica containing oxide of manganese—a semi-transparent section. After focussing by means of a lamp which was afterwards removed, about nine inches of magnesium ribbon was burned behind the section. The camera slide closed, removed, and plate developed in the dark room with hydroquinone, a very satisfactory negative resulted. Microscopical lantern slides of wood, diatoms, starch granules, and polarised light were shown to illustrate the lecture.

A discussion followed, in which the Chairman, Rev. Clementson, Messrs. B. W. Winder, Maleham, and G. J. W. Newsholme took part.

BRISTOL AND WEST OF ENGLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

MAY 25.—(Outdoor meeting.) The places visited were the Stroud Valley and Cirencester.

Brinscombe was reached about noon, and members here left the rail and trudged off towards Saperton, the first halting place. Some pretty peeps were obtained along the canal bank, and the cameras were fairly busy until three o'clock, when Saperton was reached. By the kindness of the President (Mr. H. A. Hood Daniel) a well-stocked luncheon basket was here awaiting the hungry travellers.

Mr. William Thomas Currey, of Chelvey, Somerset, was elected a member.

The walk was then continued over pleasant ground to Bathurst Park, and the seemingly interminable avenue reached which leads at length to Cirencester. The tower of Cirencester Church terminated the prospect in the dim distance, and seemed to recede before the advancing travellers.

A short time only was allowed in Cirencester town, sufficient for a hasty picture or two of the exterior of the church, which is a noble and remarkable building. The train then took members back to Stroud, whence they drove to the residence of Mr. Lush, of Standish, who had kindly invited them to partake of his hospitality. After a very pleasant hour or two at his residence, they walked across the fields to Stonehouse and took the train home.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, June 19, 1889, will be on *Printing Processes*. Saturday outing at Rickmansworth.

FIRE.—We are sorry to learn of the entire destruction by fire of the premises, stock, plant, and machinery of the Paget Prize Plate Company on Saturday last. We believe that they will be able to recommence work in a few weeks.

Correspondence.

Correspondents should never write on both sides of the paper.

JUNE MEETING OF THE PHOTOGRAPHIC SOCIETY OF FRANCE.—AN ENGLISH PHOTOGRAPHER WELCOMED.—DELEGATIONS EXPECTED AT PARIS TO COMMEMORATE THE CENTENARY OF THE INTRODUCTION OF PHOTOGRAPHY: PROPOSED BANQUET.—A HAND CAMERA.—HOW TO MAKE A RED LAMP FOR THE DARK ROOM.—A NOVEL CAMERA STAND.—A NEW MEANS OF MAKING LARGE PHOTOGRAPHS OF DISTANT OBJECTS.—HOW TO CHOOSE RED GLASS FOR THE DARK ROOM.—A NOVEL CHANGING BOX.—THE ENEMY TO GELATINE BROMIDE PLATES.—A UNIVERSAL HOLDER FOR LENSES.—PRINTING IN DIFFERENT COLOURED INKS ON THE SAME PRINT.—DONATION OF PHOTOGRAPHIC PUBLICATIONS BY MESSRS. GAUTHIER-VILLARS & Co.—PHOTOGRAPHING RACE HORSES ARRIVING AT THE POST.—HOW TO TREAT NEGATIVES.—ORTHOCHROMATIC PLATES.—AN AUTOMATIC APPARATUS.—PHOTOGRAPHY AT THE EXHIBITION.

The Photographic Society of France held their monthly meeting on Friday evening last, the 7th instant. M. Davanne in the chair. After the election of new members, the reading of correspondence, &c., the Chairman welcomed, in the name of the Society, Mr. Protheroe, of Bristol, saying that the French Society was always happy to see foreign photographers and amateurs among them.

The Secretary informed the members that the Society had received very many letters of congratulation from foreign societies on the occasion of the forthcoming centenary of the introduction of photography, and the information was received that several delegations would be sent to Paris. The Chairman informed the members that the Committee had proposed to unite in a banquet to commemorate that happy event, and to receive the foreign deputations in the most cordial manner possible. The date of the banquet will be published as soon as possible, and the Society would be happy to welcome all foreign photographers present in Paris at that time to partake of their hospitality.

A letter was read from M. Isard, of Clermont Ferrand, stating that the best toning of silver chloride proofs could be obtained by pouring water upon quicklime, then using the said water to dissolve the gold salt—the bath works much better when fairly hot.

M. Mario Carquero, the well-known maker of photographic cameras, presented a new hand camera, which he names "Le Scanty." This apparatus takes up very little room, and is light and convenient.

M. Hervé showed the members how he transformed a petroleum lamp into a safety lamp for the dark room. He informed us that he chose his lamp small enough so that an ordinary red glass gas tube would pass over the chimney of the petroleum lamp. To stop the white rays from going under the red tube, a cardboard box, having a hole in the bottom, was passed over the white glass of the lamp; this hid the white light coming through the perforated brass work of the lamp; it sustains, at the same time, the red tube of glass. The white light from the top is prevented by rolling the tin of an empty sardine box so that the light is intercepted. M. Hervé pastes a piece of red paper over one-half of the red glass tube.

M. Gorle presented another hand camera, differing in principle from others, but similar in the object to be obtained.

M. Le Breton exhibited a camera stand composed of three brass tubes, connected at the top by a triangle, as in other stands. The stand can be heightened or lowered at will by a telescope arrangement at the bottom. About five inches from the triangle on each branch of the stand is a very clever adaptation of a screw system—such as I have seen in some pencil holders; by turning the nut a little, the leg becomes longer or shorter at will. The advantage of this is great. Suppose one's head is under the focussing cloth, and the image on the ground glass is seen to be out of perpendicular, by a very slight turn of the hand the camera can be levelled immediately. It is true the same can be done with the ordinary stand by changing the position of the leg or legs, but by this system the same can be obtained in a more easy and satisfactory manner. In fact, now I contemplate upon the structure of M. Le Breton's stand, this motion is an essential part; because, in order to obtain solidity, the inventor is obliged to connect the three legs of his stand by means of a cross joint composed of three branches overlapping each other in about the middle of the stand; they are held fast as well by means of a brass screw-nut; therefore, the branches or legs of the stand cannot be moved with so much ease—nevertheless, I see that the same motion of the camera could be obtained by means of a universal socket ball adjustment, which, perhaps, would be cheaper than the other. As it is, the stand is very strong and steady, the only fault being its weight.

M. Guillinot presented the Society with the results of his experiments on endeavouring to make large pictures of distant objects. It is well known that many operators have been trying in vain to obtain this result, and have only succeeded by the use of a large telescope—which instrument is not easy to carry about, nor within the pecuniary means of the generality of the adepts of photography. It appears that with a simple camera a bird may be obtained, full size, at a distance of 500 metres—so says M. Guillinot. It appears that this gentleman places upon his camera a lens with a focus of forty-five centimetres, and the image of the distant object is focussed as sharp as possible upon the

ground glass. The latter is replaced by another lens, with a focus of five centimetres; this takes up the rays of light coming from the first lens, and the image is thus enlarged at the will of the operator. I have no doubt that this will cause some noise and great excitement, especially among military men, when it is known that the portrait of a battery can be taken some miles away from the operator.

M. Thouroude made some very useful remarks upon the red glass used in the laboratory (dark room), and warned the members of the danger of employing certain red glass which allowed the violet rays to pass through. It is not always that an ordinary spectroscope can detect these rays, said he; one must have a perfect instrument—too expensive to be in every studio. When once a piece of red glass has been obtained which is known to be safe, it is easy by its aid, and without a spectroscope, to know if another piece of red glass be good for photographic purposes.

"Take," said M. Thouroude, "an engraving, lay upon it a small piece of the red glass which is known to be good, and alongside it the glass to be tested. If the dark lines of the engraving are seen through the two glasses in the same manner—that is to say, the same intensity and colour—the glass may be counted as good, but if the black lines of the engraving, instead of being of the same colour, are grey or paler, the red glass must be put aside as useless."

M. Thouroude then presented a hand camera, the invention of an amateur. The camera is not unlike the thousands which we see at the present day, but it is in the changing box that a new feature is to be seen. He showed us that it did not require a second to change a plate, so that sixty shots could be got per minute. I will endeavour to describe how this is obtained. The changing box is formed of two rooms one above the other. The upper room contains all the plates. Each plate is held in a light brass frame. All these frames are pushed forward by a spiral spring at the back. Under the front plate is a slit communicating with the under compartment, which contains a spiral spring of the same strength as the upper one. A rolling shutter works in a groove on the top of the box, and when this is pushed home it masks the front plate and so prevents the rays from the lens falling upon the plate. When this shutter is drawn back the front plate, pushed by the spring, goes forward and takes its place. The plate is then exposed. The operator now pushes home the shutter, and this is what takes place: The edge of the shutter being about three-sixteenths of an inch wide, catches upon the top of the brass frame bearing the exposed plate and pushes it down into the lower room; by pulling the shutter back again the next plate goes forward, is exposed, and down it goes to join its companion below, and so on until all are exposed. The system is very ingenious, and, above all, simple, and will do away with all the old-fashioned changing boxes so apt to get out of order.

Some glass plates were presented to the Society simply coated with pure gelatine, in order to demonstrate upon the difficulty of preparing gelatine plates, &c., in warm weather. Large spots were seen here and there upon the surface, like small-pox upon the face of the human victim of that disease. It is now proved beyond a doubt that all the ills to which gelatino-bromide of silver plates are subject during the summer season may be traced to the decomposition of the gelatine brought on by animalcula. The only means to prevent this disease is an antiseptic, or, what is better, rapid drying in a current of air devoid of dust.

M. Molteni presented the Society with an apparatus intended to do away with the great number of heavy front boards to hold the different lenses which are required in a studio. It is well known that every lens must be screwed upon a piece of wood ready for use; sometimes the wood is warped or cracked, and time is often lost. It has been often asked if a universal adapter for all sized lenses could not be made. M. Molteni has tried to solve the difficulty in this wise: He has made a double ring large enough for the body of the largest lens of a photographer's collection to go through it. One part of this double ring is fixed to the front board by means of screws, the other part of the ring can be separated from the other, as it is mounted in the bayonet fashion. If an artist possesses ten different lenses he gets ten discs cut out of a sheet of ebonite; these discs must fit exactly the inside of the double ring. A hole must be cut in the centre of each disc according to the size of the screw on each lens. The brass ring is unscrewed off the lens, the ebonite ring put in its place, and the brass ring being screwed up nips the ebonite ring between it and the body of the lens and keeps it perfectly tight. The ebonite ring bearing the lens is then placed in the large ring before mentioned; the front or second part of the double ring is placed in its companion, and with a turn of the wrist it is sent home and nips the pieces of ebonite bearing the lens so that it cannot move. It will not take a minute now to take out the lens and change it for another. Mr. Protheroe found it so good that he begged me to solicit M. Molteni to allow him to have the one presented to take home with him to England.

Another member, M. de Villecholle, came with the intention of presenting a similar order of ideas. He does away with the front board of the camera and replaces it by a square piece of zinc, having a hole in the centre of a size to admit the back screw of the lens. This zinc plate once on the lens, the brass ring is screwed up and keeps it firmly fixed. This plan is very simple, simpler than the other, and at the hand of every photographer. The great advantage I see in both of these plans is that we no longer screw the ring or flange of the lens upon the front board, as this has been always a weak point in the camera, especially in the field,

and more so when a rapid shutter is adapted to the lens. The shock of the latter is sure, sooner or later, to loosen the screws and cause damage.

M. Gravier presented some gelatino-bichromated paper, which, after having been exposed to light under a lace window blind, was covered with different coloured fatty inks. This paper having been washed before, the Society abandoned the ink in those parts rendered insoluble by the light, whereas it stuck to those places protected from its action. The consequence was we had a pretty pattern of a window blind printed in different colours. The paper, I learn, was, and is, manufactured by M. Fisch, of Paris.

M. Gauthier-Villars, the photographic editor of France, kindly made a donation to the Society of several new books on photography lately published by him—*How to Obtain Enamels*, by Geyanet; *Permanent Pictures on Chinaware, Glass, &c.*, in Platinum, by the same author; *Photographic A.B.C.*, by W. H. Burton, translated into French.

M. de la Manna sent in some proofs for inspection, which prove sooner or later that photography will take the place of the umpire in horse races.

M. Guilleminot presented, at the last meeting of the Society, several negatives which had been under exposed and over developed no doubt, as that gentleman initiated the members into a secret process by which harmony could be obtained. The back of the negative was covered with a coloured collodion sensitive to light, the negative is laid in the bottom of a deep box (so that the rays of light should be parallel) and exposed for a short time to light. When washed the colour remains in those parts impressed by light, and leaves the collodion in those protected by the design from its influence. All practitioners can now see the value of this dodge. I must add, however, that long ago M. Germeil Bonnaud made a very interesting communication, not only to harmonise a negative, but also to intensify one when too feeble, and that by the best retoucher—light. This was sent to THE BRITISH JOURNAL OF PHOTOGRAPHY by your humble servant.

Messrs. Boissonas sent in a report of the value of orthochromatic plates and their superiority over ordinary gelatino-bromide of silver plates, especially if a yellow screen be employed. They say that the exposure is not lengthened by the interposition of the coloured screen.

M. Enjalbert has invented an automatic apparatus intended for the Exhibition. Every one now is acquainted with the weighing-machines and the sweet and chocolate apparatus, in the which, by putting a penny, one can have one's true weight, or some chocolate, sweets, matches, cigars, and what not. The automatic photographic apparatus invented by M. Enjalbert is intended to be placed in public resorts. A person desires his or her portrait, gets on the apparatus, and puts into the hole a silver half franc piece. Immediately the works are set in motion. A ferrottype plate passes under a mechanism and is coated with collodion; it is balanced in every direction on its way to the silver bath, in which it remains one minute. It then passes behind the lens and receives the impression, goes into another bath and is developed, makes its way through water into the cyanide bath, washed again, and is then plunged into a bath of alcohol, dries, then falls into an elegant brass frame, which is folded by machinery. It then makes its appearance, and is then seized by the owner, whose features it would be very interesting to study at that moment. A great deal of time and mechanical ingenuity have been employed by M. Enjalbert to complete this complicated machine, which we hope will repay him for his talent.

The French photographic department of the great Exhibition is not yet completed, nor is the Exhibition yet finished. I should counsel my readers not to come before a month if they do not desire to be deafened by the hammering or pushed about by the workmen running like busy bees in all directions. As to the English photographic department, it does not honour the nation nor please those who see it.

196, Rue Legendre, Paris.

PROF. E. STEBBINO.

SIDEREAL PHOTOGRAPHY.

To the Editor.

SIR,—Having lately read the report of the discussion which took place in London in the month of January last between Mr. Common, Mr. Clark, and the Chairman of the Camera Club (THE BRITISH JOURNAL OF PHOTOGRAPHY, February 1, 1889), on the subject of celestial photography, certain ideas have been suggested thereby which I take the liberty of putting before you.

The Chairman on that occasion (Mr. Traill Taylor) has rightly pointed out that a photographic objective ought only to present the image of a star as a geometric point without dimensions, and that this is the case no matter what be the intrinsic brightness of the star. All the photographs, however, which have been taken, even with the most perfect instruments, show definite discs, whose size increases with the brightness of the star. The attempted explanations of this kind of irradiation which have been given are scarcely very convincing. Mr. Traill Taylor attributes, with some plausibility, this curious phenomenon to reflections from the second face of the plate, which would produce an effect like that of the well-known halo in photographs, which, according to him, is due to this cause. Although Mr. Common only ventures to attribute this increase of size to a remarkable disposition of providence, he seems to me inclined to adopt Mr. Taylor's explanation.

If this explanation be correct, it involves a consequence of considerable

importance with regard to the accuracy and exactitude of the results obtained in stellar photography. As a consequence, in the case of a star situated exactly in the prolonged optic axis of the instrument, the reflection of the luminous rays from the second surface of the glass forms a conical bundle, which surrounds the luminous image of the star occupying the centre. But in the case of stars situated away from the centre of

the field matters are different; the luminous conical bundle, whose apex is the real image of the star, continues its direction obliquely, gets reflected from the second surface, and on its way back is intercepted by the first surface, where it forms an ellipse more or less elongated, whose centre will be removed the further from the true image the more oblique was the incidence of the luminous rays—that is to say, according as the star was situated near the limit of the field.

With a sufficient obliquity (such as that depicted in figure 2) the true image might be altogether outside the reflected image. It is more than probable that in practice this would not occur, as the actual obliquities are too insignificant. It is not less true that if Mr. Taylor's explanation is confirmed, the centre of the figure, which up till now has been considered as the position of the geometric image of the star, is not altogether so, and that it would be necessary to introduce a further correction in making the final reductions. It would, therefore, I think, be useful to verify directly the truth of Mr. Taylor's hypothesis.

This is the manner in which I think one might proceed. In employing a plate whose second face had been chemically silvered it is plain that the reflection would be exaggerated, and that the phenomena (due to it) would be produced with special intensity. On comparing negatives taken on plates of this kind with others on ordinary plates, or plates whose backs have been covered with a mixture of lampblack and glycerine, under equal conditions of exposure and development and of the emulsion, one would be able to ascertain the effect produced by reflection, and to allow for it in subsequent reductions, if it really exists.

Please accept, Mr. Editor, the assurance of my most distinguished consideration.

HENRY MORIZE,

Astronomer of the Imperial Observatory, Rio Janeiro.

LENSES.

To the Editor.

SIR,—There are several points in regard to photographic lenses which have often cropped up when talking to others on photographic matters which I think would be of interest to many of your readers if you could spare a little space to explain.

First, in what way do two lenses of the same focus and both working at, say, $f/45$, but one of the rapid rectilinear type and one of the wide-angle rectilinear type, differ from each other when used to cover the same sized plate?

Second, what are the disadvantages of a doublet made with two lenses similar to the front combination of a portrait lens compared with a rapid rectilinear, both working at, say, $f/8$?

I have never seen these points, which must be understood by any one with a knowledge of lens construction, elucidated.

I was in hopes that these points would have been touched by Mr. Conrad Beck in his lectures a short time since, but I cannot find that they were.—I am, yours, &c.

H. G. M. CONYDEARE.

The Hut, Ingatestone, June 4, 1889.

[In reply: 1. There will not be any difference in the resulting photograph. But it would be possible to cover a larger plate with the wide-angle lens, owing to its lenses being placed closer together than in the other. On the same sized plate there will be no difference. 2. The disadvantages are that with a doublet composed of two such lenses as specified, the field would be very round, and the marginal definition bad. To obtain uniform sharpness over a moderately large area, a very small diaphragm would have to be employed. In doublets of this class it is imperative that the lenses be of the Meniscus form.—ED.]

HYDROQUINONE.

To the Editor.

SIR,—In reference to your hydroquinone experiments on Alpha paper, perhaps it may interest you if I give my experience, which is somewhat at variance with yours. The phenomenon you describe exactly fits one case in point with my own experience, but not with Alpha paper. During

last winter I worked a good deal with gaslight and bromide paper, and used hydroquinone to some extent. My subjects being frequently *hoarfrost* pictures were well adapted to such papers, and served as a very delicate test of quality of result. I used three kinds of paper—Ilford slow bromide, Ilford, Alpha, and Morgan & Kidd's ordinary bromide. With the first paper—slow bromide (and using in each case hydroquinone, two grains to one ounce of water with hydrate of potash)—I almost invariably succeeded (time of exposure being correct). With Alpha I succeeded fairly well, but did not get quite such nice prints as with the slow bromide, or as when I used ferrous oxalate, but I have had no case of double image, such as you describe. I used fresh developer for each print, and always a *small* dose of bromide. So far my experience does not tally with your use of Alpha paper, but the strange part is that with Morgan & Kidd's bromide paper every print I tried was a failure from the cause you mention. The development was slow and delicate up to a certain point, then, when slightly more potash was added to get more force, development commenced at the edges, and gradually attacked all the darker shades of the print, producing intense blackness in a patchy way, which quite ruined the result. It is rather strange that I should succeed comparatively well with Alpha (containing chloride) and fail with a well-known brand of bromide paper, whereas I succeeded perfectly with the same bromide paper and negatives when using *ferrous oxalate*. Will you try the effect on Morgan & Kidd's paper, and see result? In that case it can hardly be a question of chloride of silver, as it is one of the best quick bromide papers in the market, and I suppose would not contain any chloride.

I find the hydroquinone to give a pleasanter-toned spirit than ferrous oxalate, not such a blue-black, more the tone of warm Indian ink as compared with cold Indian ink water colour, and softer in detail, fuller of half-tone. Ferrous oxalate prints tend to hardness, hydroquinone to softness. —I am, yours, &c.,

GEORGE BANKART,

President Leicester Photographic Society.

Penrith, Cumberland, June 4, 1889.

Exchange Column.

*• No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

Will exchange a Victoria camera with nine lenses, complete, for studio accessories.—Address, WARREN, 22, Archway-road, Highgate, London, N.

I will execute enlargements in oils, water-colour, or monochrome, in exchange for a good safety bicycle.—Address, A. HAMILTON, Kingsdown, Bristol.

Wanted to exchange, Field's Grammar of Colouring, price 3s., clean, for H. P. Robinson's Picture Making by Photography.—Address, G. ATKINSON, 40, Cambrian-view, Chester.

Will exchange Marion's half-plate camera, rapid lens, three double slides, tripod, dishes, lantern, &c., equal to new, for safety bicycle.—Address, A. HARCOURT, 52, Vicar-road, Liverpool.

I will exchange Victoria camera with four lenses, also double-back Gem camera with twelve lenses (takes twenty-four on half-plate), for a Ross' symmetrical lens, half-plate.—Address, J. SIMPSON, Photographer, 7, Sneyd-street, Staffordshire.

Wanted, good background (in oils), interior or exterior, in exchange for balustrade equal to new; send photograph of background for photograph of balustrade. Also will give new 12x10 stand (outdoor) for porcelain dish, size 24x18.—Address, BEAUX & BARNARD, Photographers, Newport, Monmouthshire.

Will exchange 180 weekly volumes of Cassell's National Library for a good five and a half or six-inch compound condenser for enlarging purposes, a quarter-plate Newman's pneumatic diaphragm shutter in perfect condition, a Grace's rainbow spectroscope, or an optical lantern to value.—Address, HERBERT CLARK, Heckmondwike, via Normanton.

Answers to Correspondents.

*• Communications relating to Advertisements and general business affairs must be addressed to "H. GREENWOOD & Co.," 2, York-street, Covent Garden, London, W.C.

All matters for the text portion of this JOURNAL, including queries for "Answers" and "Exchanges," must be addressed to "THE EDITOR," 2, York-street, Covent Garden, London, W.C. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.

THE article by Captain Himly in our last was omitted to be credited to the *Wochenblatt*.

J. G.—We removed the varnish from the transparency by placing it in a bath composed of caustic potash one ounce, and ten ounces each of alcohol and water.

GEO. FERRIS.—To remove the pyro stains from your fingers, treat them with hydrochloric acid, diluted slightly, and afterwards wash thoroughly in warm water.

P. N. W.—You may prepare the negative for being retouched by applying gum thus dissolved in benzole. But numerous other methods have been published.

WILLIAM MAYOR.—Your friend had better purify by distillation. There is no other reliable method he can adopt to suit it to photographic requirements.

S. HERBERT.—If the paper be tinted with a fugitive pigment, as most tinted albumenised papers are, it is not a matter for surprise that the tint fades on exposure to light.

J. F. BLACKMORE.—With the same brand of plates you are using we get good density in the sky with the hydroquinone developer, as made by the formula given in a previous page in this number, and should recommend you to try it. You might also with your present developer try the effect of increasing the proportion of pyro and bromide, which will favour density in the sky.

E. ELLIS.—If you have tried all the remedies for blisters you mention without success we fear we cannot help you, except by saying get a fresh brand of paper. Have you tried using the fixing bath and the salt or other solution of exactly the same temperature? We do not know the formula for the commercial retouching medium which you say is compounded of a mixture of "turps and a salt of iron."

FERRIDCYANIDE.—1. The price you are paying for hyposulphite of soda is very low; but we cannot say that for that reason it is impure.—2. Any operative chemist will supply you with *chemically* pure hyposulphite of soda. Get a little and compare it with that you are using.—3. The proportions you are employing for reducing are quite right; you may modify the action of the reducer by dilution, or employing it more concentrated, as occasion may require.

W. G. P.—Any paper maker will supply you with a suitable paper if you give him to understand what you require. Or if he does not stock the article you require, he will make it to your order. But of course you will have to take a good quantity at a time. Carbon tissue makers, as a rule, have the paper made to their order. Saxe or Rives paper answers the purpose very well, though somewhat expensive, and if you only require, say, a hundredweight or two, it will probably answer your purpose better to pay the extra price than to order a special making.

CAUSTIC says: "I have been trying to dissolve the varnish off some old collodion negatives, using methylated spirit and ammonia. With several of them it has been a failure, leaving on them dense patches of undissolved gum. You have several times given a recipe containing caustic potash, alcohol, and water; but after long search I cannot find it. Would you be kind enough to give me the proportions?"—Possibly the varnish was made with resins which are not soluble in alcohol. Hence it will be well to try some other, say benzole. Methylated alcohol, with acid, caustic potash, or soda, may also be tried, say thirty grains to the ounce. So may also methylated spirit, used warm. This seldom fails to remove the ordinary negative varnish.

I. C. A. writes: "I have got two photographs which I value very much, which are mounted and framed, but through having got damp, from damp walls, are entirely spoiled, by having a yellow mark down the centre, this being caused through a crack in the backboard. If there is any possible means in getting rid of these marks, I should feel obliged by an answer to the same through your 'Answers to Correspondents.'"—We fear that the marks cannot be successfully removed. By treating the prints with a dilute solution of bichloride of mercury the yellowness may be destroyed, but this will not restore the lost detail. The best plan will doubtless be to copy the pictures as they are, using orthochromatic plates, with a pale yellow screen. Sometimes by this method of procedure it is possible to obtain better reproductions than the originals would lead one to expect.

Mr. W. R. BAKER has shown us a new camera he has just devised, in which are certain good features. By means of a mirror placed diagonally the image on the focussing screen is seen, without the aid of a focussing cloth, until the moment before exposure. Three double dark slides, each half an inch thick, are kept in the camera itself. There are many ingenious mechanical contrivances in connexion with the slides and the manner of opening the dark shutters, but these could scarcely be understood without the aid of drawings.

"PHOTOPEL" is a very convenient form of tablet in which Messrs. Wyleys & Co., Coventry, compress pyrogallie acid. It forms the perfection of portability. Each tablet contains, in addition to the pyrogallie acid, such other substances as are from experience found to be desirable in developing negatives, lantern slides, and bromide prints. Messrs. Wyleys & Co. write: "We start out with the idea that to the amateur such a pellet will be found useful from its simplicity, and that even a professional photographer might find its portable form convenient under certain circumstances." We have tried and like the pellets very much, especially when used, as the makers advise, with caustic potash, a bottle of which accompanies each tube of the pellets.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1520. VOL. XXXVI.—JUNE 21, 1889.

WIDE ANGLES IN STEREOSCOPIC VIEWS.

PERHAPS the best way to introduce this subject is to make a brief extract from the letter of an esteemed correspondent, Sir James D. Marwick, who, *inter alia*, writes :—
